Kelp can form three morphological groups according to the canopy height and the length of the blade, namely, "canopy," "stipitate," and "prostrate" (Dayton, 1985; Duggins, 1988; Steneck et al., 2002; Alongi, 2018). *Macrocystis* spp. form massive common canopies on the west coasts of North and South America, eastern and southern Pacific region, southern Australia and New Zealand. They are, known as giant kelp, whose fronds can grow up to 45 m (Steneck et al., 2002; Wernberg et al., 2019). The kelp species *Alaria fistulosa*, *Ecklonia maxima*, and *Nereocystis leutkeana* form canopy forests up to 10 m in height (Dayton, 1975, 1985; Steneck et al., 2002). Stipitate kelps are shorter than small canopy-forming kelps and have rigid upright stipes (Dayton, 1985). Most of the *Laminaria* species are stipitate kelps, as are some species of *Ecklonia*, *Lessonia*, *Pterygophora*, *Eisenia*, *Pleurophyucus*, and *Thalassiphyllum*. Prostrate kelps lack an erect stipe and lie on the seabed at low tide (Steneck et al., 2002). Several species of *Laminaria* form prostrate kelp forests (Steneck et al., 2002).

Taxonomy

The word "kelp" is a common term for the members of the order Laminariales. Molecular studies have clarified the familial and generic relationships in the order Laminariales (Bolton, 2010). Currently, kelp comprise 9 accepted families, 59 genera, and 144 species (Guiry and Guiry, 2018). Most of the species are in the three most common families: Alariaceae, Laminariaceae, and

Lessoniaceae. The most species rich genera are *Alaria*, *Laminaria*, *Saccharina*, *Ecklonia*, and *Lessonia* (Teagle et al., 2017). The genus *Laminaria* has 29 species and genus *Alaria* has 15 species (Guiry and Guiry, 2018) (Table 1).

Geographic Distribution

There are two to three times more kelp species present in the northern than southern hemisphere (Wernberg et al., 2019). In general, kelps are cold water adapted species (Fig. 1). However, there are deep water kelp forests in the tropics in both hemispheres comprised of *Eisenia galapagensis*, *Laminaria brasiliensis*, and *L. abyssalis* (Graham et al., 2007; Santelices, 2007; Smale and Moore, 2017). *Lessonia* is widespread in the southern hemisphere and is the only genus not present in the northern hemisphere.

Abiotic Control

The distribution of kelp forests is controlled by many environmental variables such as substratum, wave action, sea temperature, light penetration through the water, and nutrients (Steneck et al., 2002). Kelp typically anchors its holdfast to rock, boulders or cobbles (Wernberg et al., 2019). The lowest temperatures kelp occur in are 5°C in the Arctic. In the tropics, although the sea surface temperature is 23–24°C, they live at depths where the temperature is 20°C (Žuljević et al., 2016; Wernberg et al., 2019). High sea surface temperature can cause physiological stress to kelp (Gerard, 1997), and consequently range contractions and reduction of kelp cover (Voerman et al., 2013; Wernberg et al., 2016; Smale and Moore, 2017).

Like all marine plants, kelps restrict their distribution to the photic zone. Their depth distribution is limited by light, and they often grow down to 40 m depth (Wernberg et al., 2019). Some deep water tropical kelps such as *Eisenia*, *Laminaria*, and *Ecklonia* can grow down to 260 m in the Indian Ocean and Mediterranean Sea where the water column is clear enough for light penetration

Table 1 List of families and genera belonging to kelp biome (Guiry and Guiry, 2018)

Family and subordinate genera	No of species	Family and subordinate genera	No of species
Agaraceae	11	Akkesiphycaceae	1
<i>Agarum</i>	4	<i>Akkesiphycus</i>	1
<i>Costaria</i>	2		
<i>Dictyoneurum</i>	2		
<i>Neogagarum</i>	2		
<i>Thalassiophyllum</i>	1		
Aureophycaceae	1	Alariaceae	25
<i>Aureophycus</i>	1	<i>Alaria</i>	15
		<i>Eualaria</i>	1
		<i>Lessoniopsis</i>	1
		<i>Orgyia</i>	1
		<i>Pleurophycus</i>	1
		<i>Pterygophora</i>	1
		<i>Undaria</i>	4
		<i>Undariella</i>	1
Chordaceae	6	Laminariales familia incertae sedis	3
<i>Chorda</i>	6	<i>Costulariella</i>	1
		<i>Feditia</i>	1
		<i>Phyllariella</i>	1
Laminariaceae	63	Lessoniaceae	32

(Graham et al., 2007; Žuljević et al., 2016). Kelp grows well in turbulent water. Wave action or water currents are important to supply nutrients, disperse propagules, and remove mucus and fouling organisms from the frond (Hurd, 2000; Gaylord et al., 2002).

Role in Ecosystems

Because kelp forms a major habitat, it is recognized as a keystone species and “ecosystem engineer” (Jones et al., 1994; Teagle et al., 2017). Its three-dimensional forest structure increases volume, heterogeneity and complexity (Teagle et al., 2017). Kelp can make environmental conditions more favorable for marine organisms by altering light penetration, water flow, physical disturbances and sedimentation (Eckman et al., 1989; Wernberg et al., 2005; Rosman et al., 2007; Smale et al., 2013). It provides feeding, breeding, and nesting habitats for a vast array of associated fauna and flora including fish, urchins, crustaceans, polychaetes, and mammals. Over 10 phyla live in kelp forests (Steneck et al., 2002). Through this support of biodiversity, kelp facilitates coastal fisheries and tourism.

Kelp is used as a fertilizer, food for farmed species, and food for people (Wernberg et al., 2019). Kelp and other macroalgae are cultivated commercially in Japan, Korea and China as human food (Correa et al., 2014). However, new uses are emerging. Kelp is a well-known source for three hydrocolloids: agar, alginates, and carrageenans. These are key ingredients for a range of products such as nutritional supplements, food flavors, food colors, texturing agents and stabilizers, agarose and bacteriological agar for microbiological and electrophoresis media, textile printing, and paper coating (Bixler and Porse, 2011). Kelp is the major food source in abalone and sea urchin farms (Correa et al., 2014). *Saccharina latissima* is a source of sugar, alginate, mannitol, and glucan. As kelp does not contain a lignin wall, it is easy to extract sugar by simple operations such as milling or crushing (Wargacki et al., 2012).

Kelp Deforestation

Natural factors such as storms, herbivory, pathogens, turbidity and temperature affect the distribution of kelp (Steneck et al., 2002). Natural deforestation events tend to be seasonal and/or transient. However, human activities can directly and indirectly affect kelp forest density and range and may be more persistent unless the causes are mitigated. Direct impacts occur due to kelp harvesting and high turbidity due to sediment runoff from land reducing light penetration (Wernberg et al., 2019). Indirect impacts are due to fisheries and climate change. Sea urchin populations increase when their predators, such as lobsters, crayfish, fish and otters, are removed by fishing (Smale et al., 2013; Costello, 2014). The natural “trophic cascade,” and thus kelp cover, is naturally restored in marine reserves when predator populations recover (Leleu et al., 2012). Climate change is affecting the intensity and frequency of storms (Steneck et al., 2002) which may impact kelp abundance. Ocean warming will result in kelp shifting its distribution to areas with suitable temperatures (Teagle et al., 2017) as has kelp and other seaweeds around Australia (Wernberg et al., 2011, 2016) and

Spain (Voerman et al., 2013; Piñeiro-Corbeira et al., 2016). In addition, herbivorous fish can move into higher latitudes from the subtropics and consume kelp (Vergés et al., 2016; Hobday et al., 2018).

Conservation

As mentioned previously, kelp forests are being fragmented due to the direct and indirect effects of climate change and fishing (Wernberg et al., 2013, 2019). A global map of the kelp biome would help conservation by indicating areas potentially suitable for kelp and improve quantification of the significance of kelp in the carbon cycle ("blue carbon"). In its absence, it is difficult to quantify the loss of kelp. However, studies using remote sensing are mapping kelp at local and regional scales (Bennion et al., 2018; Nijland et al., 2019).

Kelp is the most significant 3-d habitat in shallow cold temperate latitudes in terms of its spatial cover and height from the seabed. Other 3-d habitats are more limited in extent: seagrass occurs on sediments in a shallower depth range; cold-water coral reefs are deeper (e.g., Costello et al., 2005); and mangroves and shallow water coral reefs are largely absent outside the tropics and subtropics. The loss of kelp is thus of conservation significance because it provides a unique and extensive 3-d habitat, including shelter and food, for many species. It thereby contributes to the healthy functioning of ecosystems and fisheries. Recognizing this, Australian giant kelp forests have been listed as endangered under the Environmental Protection and Biodiversity Conservation Act in 2012 (Bennett et al., 2015; Teagle et al., 2017), and some Mediterranean kelp forests were listed as endangered under the IUCN Red List for the Adriatic (Žuljević et al., 2016). The loss of kelp due to fishery-induced trophic cascades, only recently discovered through observations in marine reserves (e.g., Leleu et al., 2012), is likely to be more globally widespread than presently appreciated. This adds to the loss of coastal kelp due to increased turbidity due to land-runoff from agriculture, forestry and urban development. Reducing such runoff, and creating marine reserves with no fishing of top predators will help kelp forests naturally recover.

Abstract

The concept “ecosystem” is here defined as a geographic area (of any size), comprised of communities of organisms and their environment, where biological and energy interactions are greater within than with adjacent ecosystems. It has been loosely used with regard to the oceans, in part because of the difficulty in determining the spatial boundaries of an ecosystem. At least 25 marine classifications have been developed for the purpose of fisheries, and environment and conservation management, and some used the term “ecosystem.” Most were based on expert opinion or ad hoc management areas, but recent studies have used data analysis to map ecosystems at a global scale. Thus, there are now global ocean ecosystem classifications that distinguish up to 28 “units” based on environmental data analysis to a depth of 5500 m. However, whether these units have unique species communities remains to be determined. It is possible that animals move between these units vertically (diel migrations) and horizontally. The increased availability of data on species distributions will enable such questions to be answered.

The concept “ecosystem” was originally used in a publication by [Tansley \(1935\)](#). He indicated that the organism should not be regarded without its ambient environment. Afterward [Lindeman \(1942\)](#) introduced the transfer of energy between the parts of an ecosystem within this concept. Moreover, [Odum \(1953\)](#) argued that the most important contribution of the concept “ecosystem” to ecological understanding was to incorporate causal relationships among the factors in an area. Later, [Odum \(1964\)](#) developed the field of “systems ecology”, which concerned “the structure and function of levels of organization beyond that of the individual and species.” In addition, [Odum \(1968\)](#) further concluded that the core of ecosystem analysis is “eco-energetic.” Dynamic ecology, including the laws of thermodynamics, had been gradually viewed as fundamental to ecosystem theory, such as the definition of productivity as a flow of energy ([Odum, 1968](#); [Patten, 1966](#); [Watt, 1968](#)). Afterwards, with the application of computers and mathematics for modeling, the emphasis of ecosystem studies changed from description to prediction ([Cherrett and Bradshaw, 1989](#)). By synthesizing previous works, [Willis \(1997\)](#) refined the definition of ecosystem as “a unit comprising a community (or communities) of organisms and their physical and chemical environment, at any scale, desirably specified, in which there are continuous fluxes of matter and energy in an interactive open system.” Ecosystem definitions include the concepts of a spatial area delimited by physical, chemical and biological energy fluxes and interactions that are stable over years ([Odum, 1968](#); [Society et al., 1989](#); [Blew, 1996](#); [Rowe, 1997](#); [Willis, 1997](#)). Here, we also define an ecosystem as an enduring, spatially bounded environment where biological and energy interactions are greater within than with other ecosystems.

Environmental classifications help distinguish marine ecosystems, and environmental conditions determine the abundance and distribution of biological species, including fisheries ([NRC, 1999](#); [Watson et al., 2003](#)). These conditions also influence variation in oxygen concentration, absorption and release of carbon dioxide, release of water vapor and aerosols ([Schimel, 2013](#)), and atmospheric concentrations of greenhouse gases ([Doney and Schimel, 2007](#); [Archer, 2010](#)). Thus knowing how many marine ecosystems exist and their distribution could contribute to understanding biogeography, managing natural resources, and modeling sea-air interactions that influence climate.

Marine environmental classifications have been developed at different scales for the purpose of fisheries, environment and conservation management ([Table 1](#)). Twelve of these maps of marine “regions” were limited to geographic zones such as the coast, continental shelves, deep sea and open oceans. They were all limited to using only a few variables or features in their design, such as ocean color and/or previous literature. Furthermore, many of them were either adjusted by or based on expert opinion ([Table 1](#)).

Some classifications were based on geography, bathymetry and/or topography ([International Hydrographic Organization, 1953](#); [Menard and Smith, 1966](#); [Smith and Sandwell, 1997](#); [Becker et al., 2009](#); [Harris et al., 2014](#)). Others used remote sensed and/or oceanographic data ([Hayden et al., 1984](#); [Longhurst, 1995, 1998, 2007](#); [Oliver et al., 2004](#); [Irwin and Oliver, 2009](#); [Silvia De et al., 2013](#); [Bailey, 2014](#)). Only [Harris and Whiteway \(2009\)](#) used both seabed and water column variables in their classification.

Species distribution data have been less used, in part because of their limited availability at global scales. However, the distribution of pelagic species has been mapped ([Rohde and Hayward, 2000](#); [van der Spoel, 1994](#); [Rytter Hasle, 1976](#); [Banse, 1964](#)), and expert workshops ([UNESCO, 2009](#)) mapped regions based on reviews of knowledge of species and environmental conditions to propose regions for conservation management for coastal ([Spalding et al., 2007](#)), open ocean pelagos ([Spalding et al., 2012](#)), and the deep-sea ([Watling et al., 2013](#)). [Costello et al. \(2017\)](#) provided the first global scale classification across all pelagic and benthic taxa, identifying 28 “realms” based on species endemism. The boundaries between some realms are only generally known because of the lack of sufficient field data in some areas, and it is likely that seasonal variation will widen the boundaries in mid-latitudes.

Perhaps the most comprehensive and objective classifications were those based on unsupervised cluster analyses. These produced the 37 three-dimensional “Ecological Marine Units” defined to 5500 m depth by [Sayre et al. \(2017a, b\)](#), 13 three-dimensional mesopelagic units by [Reygondeau et al. \(2017\)](#), 28 biological realms by [Costello et al. \(2017\)](#), and 7 ecosystems distinguished by

Zhao et al. (2018)	21 environmental variables from GMED (2014)	K-means clustering analysis using cosine similarity as distance function	7 marine ecosystems of the world ocean

analysis of 20 environmental variables by Zhao et al. (2018). The latter comes closest to representing the strict definition of ecosystems because of the more comprehensive set of data analyzed and its comparison to other classifications.

Three fully global classifications of the ocean based on quantitative environmental data analysis have been published. Oliver and Irwin (2008) applied a method which used hierarchical and k-means clustering on sea surface temperature and radiance to map 81

Fig. 1 Map of the 7-clusters marine ecosystem classification based on the 20 environmental variables. Different color zones present different marine ecosystems, while the white zones represent terrestrial regions and areas with no data.

“provinces.” Sayre et al. (2017b) used k-means clustering on six variables (temperature, salinity, oxygen, nitrate, phosphate, and silicate) to a depth of 5500 m. They distinguished 37 three dimensional regions named “Ecological Marine Units” (EMU), of which 22 comprised 99% of the ocean volume. However, there have been 20 environmental variables available for ocean surface waters at a global scale (Basher et al., 2014). These variables are derived from models incorporating satellite and in-situ sampling over one or more decades. They indicate epipelagic conditions to 200 m depth which is where most ocean productivity, variability and species occur (Costello and Breyer, 2017; Costello and Chaudhary, 2017; Costello et al., 2018). Thus, Zhao et al. (2018) used these 20 physical, biochemical and nutrient variables to distinguish seven global marine ecosystems by cluster analysis (Fig. 1). They also compared these ecosystems to the classifications of EMU and Realms to show where they coincided, and the location of environmental boundaries that may be significant in limiting species distributions, and/or be areas of ecological interest (ecotones).

There is thus a range of classifications of the oceans available. Strictly speaking only those classifications that comprise spatially bounded areas where energetic and ecological interactions are likely to be greater within that with adjacent areas, can be considered ecosystems. The best indications of such boundaries are derived from multivariate analyses of environmental data and species distributions. The increasing availability of globally modeled environmental data, and empirical species distribution data (Costello et al., 2015), are enabling more accurate and objective classifications.

Glossary

- Amplexus** A type of mating behavior in which the male grasps the female about the back and they move around together.
- Biofouling** The unfavorable accumulation of microorganisms, plants, algae, and animals on submerged structures or wetted surfaces.
- Burrower** Amphipoda that excavate holes in substrata, such as sediments.
- Carpochelate** Immovable finger of gnathopods occurring on the 5th article (carpus) in some families such as Leucothoidae, Anamixidae, and Ischyroceridae.
- Dioecious** Individuals are either male or female during their life.
- Ecdysis** The molting (shedding) of an outer skin layer.
- Ectoparasite** A parasite that lives on the exterior surface of its host such as the skin.
- Filter feeders** Amphipoda that feed by filtering suspended matter and food particles from water using setose antennae or gnathopods. They may occur on soft or on hard substrates at a variety of depths.
- First maxillae** Paired structures of the mouth used for tasting and manipulating food.
- Grazers** Amphipoda which scrape and/or pluck from the substratum to consume microorganisms, diatoms, bacteria, ciliates, and/or algae.
- Infestation** Multiple parasites living on one host.
- Inquiline** Amphipoda that are commensal or parasitic in invertebrates such as sponges and tunicates.
- Lobe** A small rounded or angular process.
- Lower lip** A bilaterally symmetrical complex forming a partition behind the mouth.
- Mandibles** The pair of jaws on the sides of the mouth.
- Maxillipeds** One pair of appendages posterior to the maxillae as the rearmost structure in the mouth part field.
- Nestler** Amphipoda that hide among algae, epifauna or in crevices.
- Parthenogenesis** A form of asexual reproduction where the gamete develops into a new individual from an unfertilized egg cell.
- Predators** Amphipoda that prey upon other organisms.
- Rostrum** A small, spine-like triangular process on the front of the head.
- Scavengers** Amphipoda that feed on [material](#) such as carrion.
- Second maxillae** Pair of lobate structures posterior to the first maxillae.
- Sessile eye** Eye without a stalk.
- Setose** Covered or have some setae, bristles, spines, barbs or quills.
- Tubicolous** Amphipoda that live in a tube.
- Upper lip** A single lobe, anterior to the mouth.
- Vermiform** Long and cylindrical, worm-like.

Abstract

The order Amphipoda are commonly known as beach-hoppers, sand-hoppers, side-swimmers, scuds, or land hoppers. Previously, they consisted of four suborders with distinct habitats, namely: Gammaridea (benthic in marine to freshwater environments); Caprellidea (marine skeleton shrimps); Hyperiidea (marine pelagic parasites of gelatinous zooplankton); and Ingolfiellidea (mainly living in interstices of aquatic gravel and sediments). However, they were recently re-classified into six suborders: Amphilochidea, Colomastigidea, Hyperiidea, Hyperipsidea, Pseudogolfiellidea, and Senticaudata (includes species formerly part of Gammaridea and Caprellidea). There are almost 10,000 described species of 221 families, 444 subfamilies, and 1664 genera of Amphipoda. Around 300 terrestrial, 1900 freshwater, and 7800 marine species exist, and most are benthic. In the sea, Amphipoda inhabit coastal, tropical, polar, deep-sea, and hydrothermal vents. Eighteen fossil species have been discovered, and all are Gammaridae and Pontogammaridae, which are mostly from the freshwater environment.

Introduction

The order Amphipoda are commonly known as beach-hoppers, sand-hoppers, side-swimmers, scuds, or land hoppers. Previously, they consisted of four suborders with distinct habitats, namely: Gammaridea (benthic in marine to freshwater environments); Caprellidea (marine skeleton shrimps); Hyperiidea (marine pelagic parasites of gelatinous zooplankton); and Ingolfiellidea (mainly living in interstices of aquatic gravel and sediments (Brusca and Brusca, 1990; Lowry and Poore, 1989; Martin and Davis, 2001). However, they were recently re-classified into six suborders: Amphilochidea, Colomastigidea, Hyperiidea, Hyperipsidea, Pseudogolfiellidea, and Senticaudata (includes species formerly part of Gammaridea and Caprellidea) (Lowry and Myers, 2013). There are almost 10,000 described species of 221 families, 444 subfamilies, and 1664 genera of Amphipoda. Around 300 terrestrial, 1900 freshwater, and 7800 marine species exist, and most are benthic. In the sea, Amphipoda inhabit coastal, tropical, polar, deep-sea, and hydrothermal vents. Eighteen fossil species have been discovered, and all are Gammaridae and Pontogammaridae, which are mostly from the freshwater environment (Horton et al., 2018).

General Biology

Morphology

The body of Amphipoda is characteristically laterally compressed and held in a curved position (Fig. 1). Other body shapes are depressed, vermiform, and cylindrical as in Phliantidae, Eopliantidae, and Caprellidae, respectively (Fig. 2). Beach Amphipoda in the family Talitridae are called sand-hoppers because they can jump by rapidly extending their bodies. Most species are <2 cm in length. Some members have bright sometimes patterned body colors of red, green, and/or blue which may resemble and provide camouflage in their habitat (Lincoln, 1979).

Amphipoda have a distinct head which often curves downward and bears two pairs of antennae that are commonly long and hairy. Some Amphipoda species have a robust rostrum on the margin between the bases of antenna one. The shape of the rostrum is a useful characteristic for recognizing the family groups such as in Oedicerotidae and Synopiidae (Fig. 3A and B). Occasionally, we

Fig. 1 Appendages of *Victorioripisa bantenensis* Arfianti and Wongkamhaeng, 2017, an eyeless marine amphipod crustacean, notes: pleopods are missing.

Fig. 2 The variety of body shape in Amphipoda (A) laterally compressed, (B) depressed, (C) vermiform, and (D) cylindrical.

Fig. 3 The distinct rostrum shape in Oedicerotidae and Synopiidae (A and B) and eye size in pelagic Hyperiididae (C and D).

see a lobe in the anterior part of the head which is useful for identifying some genera (Lincoln, 1979). Their eyes are sessile (not on stalks as in crabs, prawns, and lobsters) and generally well-developed. However, they vary considerably in size from tiny or absent (eyeless) as in subterranean or deep-water species, to massive in pelagic species (Fig. 3C and D). Their eyes are on the lateral surface of the head with some variations, such as where eyes are situated high on top of the enormous rostrum (e.g., Oedicerotidae) or well forward on a lateral lobe as in the Corophiidae. The mouth is on the ventral side of the head, with movable upper and lower lips, mandibles, two pairs of maxillae, and maxillipeds (Barnard and Karaman, 1991; Coleman, 2007; Lincoln, 1979).

The thoracic region of Amphipoda bears seven pairs of walking legs. The first two pairs have claws used in feeding called gnathopods, distinctively shaped in many species, such as in Leucothoidae (Fig. 4A and B). The five remaining pairs are for walking, climbing, and cleaning the anterior appendages, called pereopods. The next three pairs called pleopods are for swimming. Three pairs of uropods at the end of the abdomen are used for jumping or anchoring, can be very distinct in size, as in Platyischnopidae (Fig. 4C) (Barnard and Karaman, 1991).

The part of an amphipod's leg near the body is called the coxa. The gills attach on each side of the coxae 2–7. The shape of coxae can be very large as in Cyproideidae and Lysianassidae (Fig. 4D and E). In some species of Atylidae, the gills have a distinctive pleated shape (Fig. 4F). Above the anus or at the posterior end of the animal, there is a telson that can be cleft (Barnard and Karaman, 1991).

Sexual Dimorphism

The sexes in Amphipoda are separate and frequently show sexual dimorphism in their antennae, body size, and/or gnathopods. In many families, male Amphipoda (Fig. 5B) have longer antennae, and larger gnathopods and/or body size than females (McLaughlin, 1980; Iyengar and Starks, 2008). In Gammaridae, the enlarged gnathopods of males function for clasping the female during pairing for mating (Borowsky, 1984). The elongated antennae are for tactile detection (Steele, 1995) during mate searching and enhancing chemosensing ability (Kaufmann, 1994).

Reproduction

Sexual maturity in female Amphipoda is characterized by the presence of brood plates or oostegites, and in males by the enlargement of the second pair of gnathopods or the presence of genital papillae that occur as a small pair of projections in the seventh pereonal sternite. Marine Amphipoda are generally dioecious with external fertilization. Males and females pair up, such as by sharing tubes in tubicolous species or amplexus in gammarids (Borowsky, 1990; Strong, 1973). In at least one species, *Crassikorophium bonellii* (H. Milne Edwards, 1830), the fact that the male has never been seen indicates parthenogenic reproduction (Costello and Myers, 1989).

Fig. 4 The distinct gnathopods in Leucothoidae (A and B), uropod in Platyischnopidae (C), coxae in Cyproideidae and Lysianassidae (D and E), and pleated gills in Atylidae (F).

Fig. 5 Female Aoridae carrying eggs in a brood pouch (A) and male Aoridae showing enlarged gnathopods (B).

Typically, in gammarids the male will begin to pair with a female by grasping and mounting the dorsal side of a female by using the second pair of gnathopods before mating. Then, the male releases spermatophores from the ventral side of his seventh pereon into the brood lamellae (Borowsky, 1984). The embryos are deposited in a brood pouch on the underside of adult females (Fig. 5A) and will hatch into juveniles within 1–3 weeks. Juveniles remain in the pouch for some days before they are released. They have successive molts to reach maturity without metamorphosis.

Reproduction and life history are influenced by environmental factors such as food supply and temperature. Thus, Amphipoda in the low latitude areas tend to have a small body and shorter generation times than those in colder high latitudes (Aravind et al., 2007; Barnard and Karaman, 1991; Sainte-Marie, 1991).

Ecology and Behavior

Amphipoda are a crucial component in the energy flow of food webs. They link higher trophic levels, primary to secondary production, and benthic-pelagic communities. Among other vagile invertebrates in the seagrass ecosystems, Amphipoda are one of the dominant groups. Fish, birds, cnidarians, and animals such as seals prey on Amphipoda for their food (Griffiths et al., 2017; Green and Burton, 1987; Michel et al., 2016).

Amphipoda are sensitive to a broad range of aquatic pollutants. Because they live well in laboratory conditions, have a short direct life cycle, and are easy to handle and culture, they are popular organisms for ecotoxicology (Costa and Costa, 2000; Mann et al., 2010). In an experimental study, Caprellidae were considered as food for fish in aquaculture (Baeza-Rojano et al., 2014).

Amphipoda utilize diverse food resources and species may be filter, deposit, and suspension feeders; as well as grazers, predators, scavengers, parasites, and commensals (Bousfield, 1987; LeCroy et al., 2009; Watling, 1993). Most Amphipoda species are free-living, but some species are parasitic (Table 1). Studies on pelagic Amphipoda reported their vertical migration toward the sea surface during the night (Brusca, 1967, 1973; Waterman et al., 1939).

Species of the Suborder Hyperiidea are pelagic but also recognized as parasites in gelatinous zooplankton. A family from this suborder, that is, Cystisomatidae is distinct among other pelagic Amphipoda due to their large size (>100 mm in length) and transparent body, permitting us to see the internal organs (Brusca, 1981). The family Phronimidae have a unique behavior. They excavate the internal tissue of their prey such as salps, doliolids, and pyrosomes to form a transparent barrel-shaped house (Harbison et al., 1977; Hirose et al., 2005; Laval, 1978; Zeidler, 2004).

The family Cyamidae are all parasitic, known as whale lice, and are ectoparasites that crawl on the skin of cetaceans. This parasitic family is little known due to its specialized natural habitat—whales that are constantly moving and difficult to study. It is believed that infestations of Cyamidae are only possible during cetacean mating or from cetacean mother to calf, as they cannot swim well freely. Cyamidae will die if they lose their grip on their host (Iwasa-Arai and Serejo, 2018; Pfeiffer, 2009).

Calliopiella michaelsoni Schellenberg, 1925, a species from the family Calliopiidae, lives in a commensal association with gastropod molluscs (snails) to protect them from desiccation and solar irradiation. *Cardiophilus baeri* G.O. Sars, 1896, of the family Behningiellidae, lives in the mantle cavity of bivalve molluscs and gets protection and food from their host's feeding activities (Brattegard, 1963; Pirlot, 1932; Vader, 1972). Leucothoidae are also commensal Amphipoda living inside the body cavities of sessile invertebrates, particularly sea squirts and sponges (Thomas and Barnard, 1983; Thomas and Klebba, 2007).

Species of *Dyopodes*, a genus from the family Dulichiidae, secrete threads of mucus and a solid spinning thread from their specialized setae and pereopods 3–4, to construct a mast-like structure that indicates their territory and from which they capture food using their setose antennae (Mattson and Cedhagen, 1989). When a predator approaches, they move down the mast and clutch it lengthwise to make them less accessible to the predator. The amphipod family Cyphocarididae are predators of other amphipods, cladocerans, ostracods, and copepods (Yamada and Ikeda, 2000; Haro-Garay, 2003). Their body can glow (bioluminescent) as a feeding strategy to catch prey in their deep-sea habitats (Bowman, 1967; Dahl, 1979; Hessler et al., 1972).

Caprellidae are clinging Amphipoda that mostly prey on small invertebrates. The 2nd gnathopods of males have a poison tooth. The males use it for fighting other males until the death of the opponent (Takeshita and Wada, 2012). While expecting to ambush the prey, they will patiently sit and motionless for long periods with praying-mantis style body posturing. Thus, Caprellidae are also known as praying mantis crustaceans (Guerra-García and Lowry, 2009; Lowry and Stoddart, 2003).

Table 1 Variety of lifestyles, habitats, and environments of the order Amphipoda

(+) indicates present, (—) indicates absent.

As do all Aoridae, *Microdeutopus gryllotalpa* Costa, 1853 builds and inhabits individual tubes on solid substrata. They grab food resources that pass by the tube entrance. The food can be consumed directly or can be stored by gluing it to the tube for later use. Inside the tubes may be occupied by a male and female adult, or after copulation, only a brooding female. After copulation and the female having molted, the male will leave the tube voluntarily (Borowsky, 1980; Myers, 1971).

The genus *Jassa* from the family Ischyroceridae are well known as biofouling organisms and can be an initial colonizer and dominate marine biofouling systems (Barnard, 1958). As tubicolous Amphipoda, they construct tubes on floating, solid and artificial surfaces (rafts, the hulls of ship, shipwrecks), among hydrozoans, or algae (Lincoln, 1979), using a silk produced by spinning glands in pereopods 3 and 4 (Lowry, 1981; Beermann and Franke, 2012). Their tubes can attach to each other forming

thick mats with detritus, attached to various hard substrata, and they can cover clean substrata at high densities (Barnard, 1958; Dixon and Moore, 1997).

Introduced and Invasive Amphipoda

Species that are transported by human activities outside their native distributional range are termed introduced species. If they spread and/or cause harm to the environment, economy or human health, they are called invasive species. Around 5%–20% of introduced species are invasive and have negative impacts (IUCN, 2018).

At present, 58 marine, brackish, freshwater, and terrestrial Amphipoda are categorized as introduced by the World Register on Introduced Marine Species (WRiMS, Ahyong et al., 2018). Once invasive, Amphipoda can disturb the stability of an ecosystem by rapidly dominating the community and displacing native species. They also reduce biodiversity in the system through competition and predation (Cohen and Carlton, 1998; Kennish, 2002). Most introduced species are aquatic, however, some terrestrial amphipods such as *Arcitalitrus dorrieni* (Hunt, 1925) was introduced to Europe among plants imported from Australia (Costello, 1993).

Marine

Introduced Amphipoda are mainly marine and from the family Corophiidae (Ahyong et al., 2018). *Monocorophium sextonae* (Crawford, 1937) may have been introduced to Britain and Ireland among fouling on ships from New Zealand (Costello, 1993). Other introduced species in marine environments are *Elasmopus pecteniscus* (Spence Bate, 1862) and *Stenothoe gallensis* Walker, 1904. These species were introduced to the Mediterranean Sea through the Suez Canal. Due to the high number of introduced species detected, the Mediterranean Sea is the sea most affected by biological invasion (Costello et al., 2010; Strefaris et al., 2005; Zenetos et al., 2010). Two species of *Aoroides*, *A. semicurvatus* Ariyama, 2004 and *A. curvipes* Ariyama, 2004, native to Asia, were introduced into European seas through oyster transfers and shipping (Gouillieux et al., 2016).

Freshwater

Invasive Amphipoda are mostly reported from the freshwater environment. In Europe, introduced freshwater Amphipoda have led to the displacement of native Amphipoda (Costello, 1993; Dick, 1996). The displacement is through differential aggression, mutual predation, shorter generation times or higher fecundity, and different environmental tolerances (Dennert, 1974; Dick et al., 1993, 1995).

The Ponto-Caspian (Black Sea, Caspian Sea, and Sea of Azov) species *Dikerogammarus haemobaphes* Eichwald, 1841 (demon shrimp) and *Dikerogammarus villosus* Sowinsky, 1894 (killer shrimp) have invaded European freshwaters and are predicted to invade North America and worldwide in the future (Bovy et al., 2015; Rewicz et al., 2014). Other freshwater gammarids that have been introduced and are invasive in European waters are *Gammarus pulex* (Linnaeus, 1758) (to Ireland from Britain), *Gammarus tigrinus* Sexton, 1939 and *Crangonyx pseudogracilis* Bousfield, 1958 from North America to Europe.

The expansion of invasive species was accelerated by the interconnectivity of waterways through canals in Europe, ship ballasts, and bilge waters of international transportation (Nunes et al., 2015; Jazdzewski and Konopacka, 2002). Their success to out-compete resident species is aided by early sexual maturation, rapid growth rates, high fecundity, strong predatory behavior, opportunistic feeding habits, and high adaptability to wide ranges of temperature and salinity (Grabowski et al., 2007; Kinzler et al., 2009; Rewicz et al., 2014).

Conclusion

In summary, Amphipoda are small, shrimp-like crustaceans without a planktonic larval phase. They have a variety of behaviors, including mate guarding, and tube-building. As suspension and deposit feeders, and predators, they provide an important link between primary producers and predators in ecosystems. The majority are free-living, but some are parasites or commensals. Globalization and human activities have led to the arrival of several species outside their native range, some of which have become invasive in freshwaters.

Abstract

Giant clams are conspicuous bottom-dwellers of the tropical Indo-Pacific coral reefs. To date, there are 12 recognized species divided into two genera (*Hippopus* and *Tridacna*) in the subfamily Tridacninae. Because of their large body sizes and shallow distributions, giant clams are readily found and collected, and have been a reliable traditional coastal resource (food and shells) throughout their geographic range. Unfortunately, the unsustainable levels of exploitation, coupled with loss of habitats, pollution and climate change, have threatened the survival of wild giant clam populations. Due to the nature of their reproduction (e.g., late reproductive maturity and broadcast spawning), giant clam populations are highly sensitive to stock depletion, which reduces fertilization success and subsequently, recruitment rates. To better safeguard the remaining giant clam populations, conservation actions such as listing in the CITES Appendix II and the IUCN Red List of Threatened Species have contributed to stemming further declines, and local laws have helped to manage subsistence fishing practices and curtail illegal fishing. Mariculture also has a complementary role in the conservation of giant clams, as it can produce large numbers of individuals to assist in the restoration of depleted populations. In addition to these existing measures, it is important to meaningfully engage with all stakeholders (e.g., fishers, traders, and public) on the ecological value of giant clams and consequences of overexploitation to bring about changes in attitude and lead to sustainable fishing practices.

Introduction

Giant Clams (Subfamily Tridacninae)

Giant clams are large marine bivalve molluscs that live in close association with the tropical coral reefs (Neo et al., 2017). The biggest species, *Tridacna gigas* (also known as the true giant clam) could grow over 1-m long (Rosewater, 1965) and weigh more than 250 kg (Lucas, 1994). While the smallest species of giant clams, *Tridacna crocea* (also known as the burrowing giant clam) can reach up to 15-cm long (Rosewater, 1965), it is still larger than most bivalves. These conspicuous shelled animals are readily recognizable by their large body sizes, colorful outer mantle tissues, and heavy fan-shaped shells. Unlike other bivalves, giant clams cannot fully close their shells. A common sedentary inhabitant on the Indo-Pacific coral reefs, the giant clam provides physical habitat structure and filters phytoplankton (Neo et al., 2015a), and is considered an indicator of reef health by Reef Check (Hodgson, 2001). Being a long-lived marine species, giant clams are sentinels on the reefs that may provide indications of long-term reef health and conditions.

The giant clams are scientifically classified in the order Veneroida, family Cardiidae, subfamily Tridacninae, consisting of two genera: *Hippopus* and *Tridacna* (Schneider, 2002). This means that the true cockles are their closest relatives. Currently, the 12 recognized species (Fig. 1) are mainly distributed along the shallow coasts and coral reefs from South Africa to the Pitcairn Islands, and from southern Japan to Western Australia (Neo et al., 2017). Geographically, *T. maxima* and *T. squamosa* are the most widespread, followed by the intermediate-range species, *Hippopus hippopus*, *T. gigas*, *T. derasa*, *T. noae*, and *T. crocea*, and

restricted-range species, *H. porcellanus*, *T. mbalavuana* (formerly known as *T. tevoroa*), *T. squamosina* (formerly known as *T. costata*), *T. rosewateri*, and *T. lorenzi* (Neo et al., 2017).

Biology of Giant Clams

Giant clams are simultaneous hermaphrodites: maturing first as males between 2 and 6 years of age, and later developing functional hermaphroditic gonads that produce both mature sperm and eggs (Lucas, 2014). During spawning, the release of sperm before eggs is assumed to prevent self-fertilization (Ellis, 1998), and depending on an individual's size, the number of eggs released varies from

tens of thousands (Neo et al., 2011) to hundreds of millions (Lucas, 1988). Their larval life cycle (Fig. 2) lasts for approximately 9 days prior to settlement (Crawford et al., 1987; Ellis, 1998). Fertilized eggs first develop into trochophores within 12–24 h and into shelled swimming veligers within 36 h of fertilization (Ellis, 1998). The older pediveligers (7- to 8-days old) then develop a foot that is capable of actively searching and settling onto suitable substrata (Neo et al., 2009, 2015b). Pediveligers then continue to metamorphose into juvenile spats, where they thicken and enlarge their shells and overall body size. Juvenile giant clams remain motile using their foot for locomotion (Huang et al., 2007), and search for suitable substrata (Neo et al., 2009, 2015b) or conspecifics (Sim et al., 2018) before attaching themselves on the seabed with byssal threads. Despite their high fecundity, size distributions of giant clams suggest that recruitment of juvenile clams is low, implying that mortality of early pelagic or postmetamorphic stages is high (Yamaguchi, 1977).

Like most bivalves, giant clams are filter feeders. Larvae, juveniles and adults capture suspended particulate food such as phytoplankton, zooxanthellae, micronutrients, and trace metals via their ctenidia (gills) (Fitt, 1993; Klumpp et al., 1992). In addition, giant clams obtain food from their symbiosis with zooxanthellae that live within their tissues (Belda and Yellowlees, 1995). In their early life history, eggs and larvae (called veligers) are free of symbiotic zooxanthellae (Mies et al., 2017a; Waters et al., 2016), and only in the adults will zooxanthellae be present in dense masses (Griffiths and Klumpp, 1996). The highly motile veliger larvae acquire their symbiotic microalgae via ingestion at an early stage, manifesting within their guts and selectively not digested (Nakayama et al., 1998; Waters et al., 2016). Unlike in corals, the zooxanthellae are extracellular in giant clams, occupying a tubular system within the mantle tissues (Norton et al., 1992). They serve a similar symbiotic function of using the host's waste products to produce the bulk of photosynthates (e.g., glucose, amino acids) taken up by host giant clams (Goreau et al., 1973; Ishikura et al., 1999). The steady and continuous supply of nutrients from zooxanthellae afforded the giant clams a nutritional advantage over nonsymbiotic bivalves (Hawkins and Klumpp, 1995).

In early larval stages, the free-swimming trochophores and veligers can alter their depth distribution and actively select settlement sites (Neo et al., 2015b). Subsequently, veligers metamorphose into pediveligers, which have a foot used for crawling on the seabed. The foot is also covered in cilia that allows the giant clam larva to sense and orientate to its surroundings in search of shelter (Dumas et al., 2014; Neo et al., 2009). The pediveligers, over time, become increasingly sedentary but remain mobile as they grow into juveniles and adults (Huang et al., 2007; Suzuki, 1998). Interestingly, juvenile clams have been shown to move more at night, potentially an adaptation to avoid visual predators (Soo and Todd, 2014; Suzuki, 1998). Juveniles were also observed to move nonrandomly and clump towards conspecifics (Huang et al., 2007), and further experiments have found that aggregative behavior have trade-offs between predator defense and conspecific competition (Sim et al., 2018). Some notable behavior in adult giant clams include self-righting (Fankboner, 1971), shadow responses (Stasek, 1965), and squirting reflexes (Neo and Todd, 2011), which can aid as antipredatory defenses.

Ongoing Threats and Challenges

Utilization of Giant Clams

Giant clams have benefitted people for millennia (Richter et al., 2008), and have long been an important component of fisheries in the Indo-Pacific region. Their shallow distribution, conspicuous appearance, and sessile nature make them easy to harvest with simple fishing gear. During reef gleaning, nonspecific fishing, and free-diving (Hviding, 1993), giant clams are usually opportunistically collected, or their flesh excised from the shells with knives and/or wooden sticks (Kinch and Teitelbaum, 2010). SCUBA

Fig. 2 Life cycle of the giant clam.

and improvised diving apparatus such as the hookah gear (a simple surface air feed) have also been used to extract clam meat underwater, hence obviating the need to retrieve the heavy shells.

Food

The giant clam forms a significant part of the diet of people living in Oceania and Southeast Asia (Munro, 1983). The entire clam, except for its kidneys, can be eaten (Hviding, 1993), and their adductor muscles are highly valuable food in Southeast Asia (Pearson, 1977). Almost all species of giant clams have been extensively used, and greater domestic needs led to an increase in subsistence fishery during the early 1970s (Juinio et al., 1989; Wells, 1982). The demand of clam meat for commercial sale had also caused rapid stock reductions across their range in the Indo-Pacific region (Dawson and Philipson, 1989; Kinch and Teitelbaum, 2010). Substantial markets for giant clams as food existed in Okinawa and Taiwan when surveyed between the 1970s and 1990s (Dawson and Philipson, 1989). In Okinawa, clam meat is considered a delicacy and remains an important element in traditional Japanese food (Anne Claus, 2017). In Taiwan, the adductor muscles once fetched prices up to US\$30 per kilogram (Shang et al., 1991). Wild populations in the Pacific Ocean were also threatened by illegal poaching carried out by Taiwanese clam vessels in foreign waters from 1969 to 1976 (Hirschberger, 1980; Pearson, 1977). Large-scale poaching continues to be a major persistent threat, as various countries (Australia, Cambodia, Malaysia, and the Philippines) have reported an increase in illegal clam fishing boats within the last 5 years (Neo et al., 2017). Commercial harvesting of wild stocks is now banned in most countries, but poorly regulated subsistence fishing can still threaten existing stocks.

Shells

There is a long history of their calcified shells being used as materials and ornament, and Table 1 provides an overview of the various uses of giant clam shells. Previously, giant clams were collected in large quantities for the ornamental shell trade, mostly exported to Japan, Australia, the United States, and Europe (Tisdell, 1994a). It was perceived that the commercial value for shells was greater than meat and adductor muscle (Juinio et al., 1987; Tisdell, 1994a). Shells were traded for decorative and utilitarian purposes, from high-value products such as jewelry to low-value uses such as aggregate in building materials (Heslinga, 1996). Also, species with colorful and large shells (e.g., *H. hippopus*, *H. porcellanus*, *T. gigas*, and *T. squamosa*) typically fetched higher prices than the smaller *T. maxima* and *T. crocea* (Juinio et al., 1987). Consequently, the supplies of shells became severely limited due to overexploitation of natural stocks (Juinio et al., 1989) or export bans (i.e., the Philippines; Neo et al., 2017). While the international trade in giant clam shells (and meat) are closely regulated by international legislation (such as CITES), the sale of shells within domestic markets remains open and popular among tourists and shell collectors (Fig. 3A and B). An example of the largest *Tridacna* shell markets today is found in China, where large fossilized shells are made into handicrafts (Larson, 2016; Fig. 3C and D).

Table 1 A summary of the various uses of giant clam shells

Use(s) of giant clam shells	Where?	Information source(s)
● Artifacts used as tools and burial ornament ● <i>Tridacna crocea</i> shells used to weigh down fishing nets ● <i>Tridacna squamosa</i> shells used as talismans against evil influences ● <i>Tridacna</i> adzes—prehistoric culture of Southern Ryukyu ● Fossilized giant clam shells made into carvings and sculptures ● Body ornament (necklace and bangles) used in traditional costumes and worn during festive seasons or weddings ● Terrazzo tiles	Ryukyu Archipelago	Asato (1991), Kinoshita (1992), and Nishihara (2004)
● Accessories, carvings, and sculptures ● Clam shell rings—traditional exchange currency and ceremonial objects ● Sacred containers—holy water font ● <i>Tridacna</i> adzes—a tool used for smoothing rough-cut wood in handicraft ● <i>Tridacna</i> shell plaques—associated with burials ● Weaponry—to throw down on approaching enemies ● Axe heads	Hainan Island, China Kedat, northern Sabah, Malaysia Karimun Java, Pulau Seribu, Indonesia Solomon Islands (Melanesia)	Larson (2016) Albert et al. (2017) Brown and Muskanofola (1985) Hocart (1931), Hviding (1993), Miller (1979), Richards and Roga (2004), Waite (1983), and Willey (1896)
● <i>Tridacna</i> adzes—a tool used for smoothing rough-cut wood in handicraft ● Domestic tools—water troughs for pigs ● Engraved <i>Tridacna</i> shell discs—cosmetic palette, decorative ornament	Manus Islands, Papua New Guinea (Melanesia) Pohnpei, Eastern Caroline Islands (Micronesia) Tuvalu (Polynesia) Libya, Iran, Iraq, Israel, Italy, Jordan	Dawson and Philipson (1989) Ayers and Mauricio (1987) Dawson and Philipson (1989) Brandl (1984, 2001), Reese (1988), and Reese and Sease (1993)

Fig. 3 Giant clam shells are sold as tourist souvenirs (A) and intricate carvings (B). The raw materials for large carvings are often the fossilized shells (C and D) that were collected from dredging of seabed.

Live aquarium industry

Growing in popularity, the aquarium trade for giant clams has become increasingly significant in the last three decades (Mies et al., 2017b). Around the early 1990s, feasibility studies were conducted in Australia and the United States to explore potential markets for giant clams as aquarium specimens (Shang et al., 1991; Tisdell, 1994b). Aquarium retailers showed interest in selling the colorful invertebrates, but expressed concerns over the lack of knowledge of aquarium care, transportation, and availability of stocks. Over time, the build-up of knowledge (e.g., Bell et al., 1997a,b) boost retailers' confidence in selling giant clams as aquarium pets. In 2001 alone, more than 100,000 live giant clams were internationally traded for the aquarium industry (Wabnitz et al., 2003) and that number has since been growing. The major countries presently exporting for the aquarium trade are Viet Nam, French Polynesia, and Palau (Mies et al., 2017b). Based on the CITES Trade Database, approximately 50% of traded specimens are cultured (CITES, 2018). However, Mies et al. (2017b) highlighted discrepancies in data reporting, pointing out the lack of traceability (i.e., whether a specimen is wild or aquacultured) and underestimated numbers of traded clams in the CITES database.

Deterioration and Loss of Habitats

The pressure of human-induced activities threatens the health of coral reef environments and hence the survival and growth of giant clams that live in them. A global meta-analysis for *T. maxima* revealed that, except for areas with very low human population density (<20 inhabitants per 10,000 m² of reef), densities of giant clams decreased with increased human presence (Van Wynsberge et al., 2016). In the northern Red Sea, abundance of giant clams was higher at sites further away from anthropogenic sources and implied that the main stressors were degraded habitats, tourism, and water pollution (Mekawy and Madkour, 2012). Environmental stressors such as reduced salinities (e.g., attributed to extended periods of heavy rainfall) could also significantly lower the survival, growth and photosynthetic performance of giant clams (Maboloc et al., 2015). Urbanization of coastal areas has been shown to negatively impact giant clam population numbers. For example, many of the reefs in Singapore where giant clams were previously found have been buried as a result of large-scale land reclamation projects (Neo and Todd, 2012). Sediment stress, a consequence of coastal development, may reduce photosynthesis and increase respiratory demands in giant clams (Elfving et al., 2001).

Climate Change

Giant clam's unique symbiotic relationship with zooxanthellae makes them particularly susceptible to the effects of warming oceans. Extremes in either temperature or ultraviolet irradiation due to climate change can lead to poor growth, bleaching (Fig. 4), and higher mortality in giant clams (Andréfouët et al., 2013; Leggat et al., 2003). Ocean acidification has also been demonstrated to exert detrimental effects in juvenile giant clams, where experimental evidence showed that they exhibit negative shell growth (Waters, 2008) and lower survival rates (Watson et al., 2012), when exposed to increasing carbon dioxide levels (~600–1000 µatm

Fig. 4 Like corals, the giant clams may become thermally stressed and expel their photosynthetic symbionts. This causes their tissues to turn white, and the extent of bleaching may differ between species. During the 2016 bleaching event, some individuals of *Tridacna gigas* showed partial bleaching at the Bolinao Marine Laboratory (Bolinao, Pangasinan) in the Philippines (A), but most *Tridacna maxima* showed full bleaching at the hatchery in Singapore (B and C).

$p\text{CO}_2$). Responses of early life-history stages to the effects of climate change stressors are generally poorly understood; with only a single combined effects study demonstrating that salinities at 27 and 32 PSU had no significant effect on larvae survival but mortality increased at the higher of two temperatures tested, namely 22.5°C and 29.5°C (Neo et al., 2013a). Climate warming and acidification can lead to bleaching of stocks in hatcheries, and cause problems of algal overgrowth, poor shell precipitation, and possibly premature spawning patterns, which are all undesirable for spawning and rearing of larvae and juveniles. Thus, climate change effects may lead to lower productivity and/or survival of clams (Wilkinson and Buddemeier, 1994), raising costs for mariculture.

Consequences of Declining or Depleted Giant Clam Populations

Giant clam populations are highly sensitive to stock depletion because their reproductive success in nature requires the synchronized broadcast spawning among conspecific clams (Lucas, 1988). Synchronous spawning in giant clams is dependent on the chemical cues found on the eggs (Munro et al., 1983), although it is not understood how a clam “decides” to release which gamete type during reproduction. Upon dispersal of eggs by water currents, the chemical cues present then induce other neighboring clams to release sperm, thus allowing fertilization of eggs by sperm from different clams (Braley, 1984). Sadly, as threats aforementioned still persist today, the number of viable spawning individuals is rapidly declining. Giant clam populations consequently face imminent decline due to poor reproductive success, especially when densities in nature fall below certain (as yet undefined) levels (Beckvar, 1981; Gwyther and Munro, 1981). In areas with low densities, it has been proposed that collecting and aggregating mature giant clams in close vicinity of each other could assure greater success in fertilization (Gwyther and Munro, 1981; Huang et al., 2007). Wild stocks may also recover via the dispersal of planktonic larvae from other reefs brought in by prevailing currents (Neo et al., 2013b). Such recovery, however, may take decades if coral reefs are isolated and/or currents are unfavorable. So, methods for restocking giant clams have been developed (e.g., Waters et al., 2013).

Conservation Measures

Legislation and Regulations

Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES)

Giant clams were identified as species to be included in CITES due to rapid exploitation of their wild populations in the early 1980s (Wells, 1982, 1997). All giant clam species are listed in the Appendix II of CITES, which consists of species that are not necessarily now threatened with extinction but may become so unless trade is closely controlled. All living or dead specimens, including all readily distinguishable parts and derivatives, are subject to the Treaty’s provisions for Appendix II species. CITES also states that the international trade in giant clams is permitted only if the relevant export and import certifications are issued by Parties. While dated, an earlier assessment of CITES role highlighted its shortcomings in the management of giant clams (Wells, 1997), which remains relevant for discussion. First, the effectiveness of enforcing CITES is largely dependent on whether countries involved in the trade are signatories to the Treaty, or if a nonsignatory is trading with the signatories (i.e., to trade, an equivalent of

CITES permit documentation is required from nonsignatory). Second, the scope of CITES Treaty does not manage domestic trade of giant clams within countries, regardless of their status as a Party member. Despite these limitations, the Animals Committee of CITES holds regular meetings to review trade levels of listed species and provides updates to Parties such as the animal's taxonomy and nomenclature (UNEP-WCMC, 2018).

International Union for Conservation of Nature (IUCN) Red List of Threatened Species

Giant clams were included in the first volume of the IUCN Invertebrate Red Data Book (Wells et al., 1983), which highlighted the urgency to better manage their levels of exploitation. Of the 12 recognized giant clam species, nine of them have been assessed and listed on the IUCN Red List of Threatened Species (IUCN, 2018). Four species are listed as Vulnerable: *T. gigas*, *T. derasa*, and *T. rosewateri*, based on the rate of decline of remaining wild stocks; *T. mbalavuana*, on the basis of its small and declining "area of occupancy" (Wells, 1997). *Hippopus hippopus*, *H. porcellanus*, *T. maxima*, and *T. squamosa* are listed as Lower Risk: Conservation Dependent on the basis of decline and disappearance of many populations. *Tridacna crocea* was initially excluded in the earlier assessments due to insufficient data (Wells, 1997), but was reinstated in the 1996 Red List and now listed as Lower Risk: Least Concern. *Tridacna noae*, *T. squamosina*, and *T. lorenzi* are not yet on the Red List as these species were recent rediscoveries, where data on wild stocks are limited. Also, the current Red Listings for giant clams are dated (i.e., 1996) and thus, require urgent updating to reflect current status quo of species.

Local management and enforcement efforts

Across the Indo-Pacific region, efforts to reintroduce giant clam species in places where they have been extirpated or for culturing purposes have been on-going but overall, these programs have met with limited successes (e.g., Teitelbaum and Friedman, 2008). At national level, the focus of giant clam management is lowering exploitation (see Neo et al., 2017 for detailed conservation efforts implemented throughout Indo-Pacific). For instance, some coastal communities in the South Pacific have placed stricter measures to alleviate fishing pressures, such as banning clam fishing for commercial use, setting minimum size limits for subsistence harvesting, imposing harvesting quotas or bag limits, restricting clam fishing to free diving only, and banning the use of mechanical fishing equipment (Andréfouët et al., 2013; Kinch and Teitelbaum, 2010). Results of these implemented measures vary among these South Pacific nations as it depends on the levels of exploitation (i.e., a highly exploited population will take a longer recovery time) and willingness to adopt these practices (Lucas, 1997). In addition to these measures, several countries have specific laws to protect their giant clam stocks, and Table 2 shows the level of protection given to these endangered invertebrates. Despite these collective efforts, illegal clam fishing by coastal communities still remains prevalent in many of the mentioned countries, probably due to its traditional importance as a coastal resource, coupled with the lack of manpower and funding to support monitoring, surveillance and law enforcement (Neo et al., 2017).

Mariculture of Giant Clams

The development of mariculture techniques for giant clams was spurred on by the rapid decline in natural populations due to overexploitation throughout much of their distribution (see Ongoing Threats and Challenges). Compared to other marine molluscs, the mariculture of giant clams is a relatively recent development, but has experienced rapid progress since its initiation in the 1980s (e.g., Bell et al., 1997a; Braley et al., 2018; Crawford et al., 1987; Ellis, 1998; Fitt, 1993; Heslinga, 2012, 2013; Lucas, 1994; Mies et al., 2017b). Like other aquaculture farming, most giant clam farms operate on a commercial (or semicommercial) basis, with the goal of efficient production of primary products (meat and shells) for various markets (Lucas, 1997; Mies et al., 2017b). While the mariculture of giant clams is not necessarily for conservation or sustainable exploitation of resources, it can provide cultured juveniles for restoring or enhancing wild populations (e.g., Kinch and Teitelbaum, 2010; Waters et al., 2013). Thus, supporting conservation and facilitating sustainable harvest (Lucas, 1997; Heslinga, 2012; Waters et al., 2013; Moorhead, 2018).

Restocking reefs with cultured giant clams

Mariculture and restocking of giant clam populations have proven to be effective (e.g., Gomez and Mingoa-Licuanan, 2006), although these efforts require long-term commitment and monitoring. There exist examples in Micronesia, the Philippines (Fig. 5), and Japan where mariculture and restocking have maintained momentum for over 20 years (Bell, 1999; Gomez and Mingoa-Licuanan, 2006; Kakuma and Kamimura, 2011). In addition, many of the cultured juvenile clams were shipped around the Indo-Pacific region in 1980s and 1990s, matured in ocean nurseries at the destination countries, and then used as breeding stock in local hatcheries. Aside from boosting giant clam numbers via restocking, another desired outcome is the production of local recruits by these restocked clams. There is firm evidence of this from Yap (Federated States of Micronesia) and the Philippines from restocked *T. derasa* and *T. gigas*, respectively (Cabaitan and Conaco, 2017; Neo et al., 2017). These examples are encouraging as they confirm that restocking programs can achieve reproductive sustainability, and eventually provide viable breeding stock to support local hatchery programs. Restocking is not without its challenges (e.g., Benzie and Williams, 1996; Lucas, 1997), but four decades of experience in this endeavor have shown that the most reliable approach is to implement well-managed, financially sustainable giant clam hatcheries and well-defended ocean nurseries (Heslinga, 2013).

Table 2 A brief overview of existing legislations pertaining to the in-situ protection of giant clams

Country	Law and regulation
Australia	The harvest and trade of giant clams managed under the Environment Protection and Biodiversity Conservation Act 1999 (EPBC Act)
China	Protected under the Marine Environment Protection Law of the People's Republic of China (Li, 2013). <i>Tridacna gigas</i> is the only species listed as Category 1 protection at national level, which is the highest protection afforded in China under their Wild Animal Protection Act
Cook Islands ^a	Gathering of giant clams for export and sale is prohibited under several by-laws such as the Aitutaki Fisheries Protection By-Laws (1990) and Penrhyn (Prohibition on Exportation of Pasua) By-Laws (2007)
Federated States of Micronesia	Only Yap and Kosrae states have laws regarding use of giant clams (Smith, 1992). The Yap State Code (Title 18, Section 1006, Protection of clams) prohibits harvest of giant clams for commercial sale, but not enforced. Under the Kosrae State Code Section 13.523, a sanctuary area is declared for the purpose of protecting giant clams
Fiji ^a	Under the Fisheries Act of 1942 (Cap 158), the export of giant clam meat from Fiji of the following species (<i>Tridacna derasa</i> , <i>T. squamosa</i> , <i>T. maxima</i>) is prohibited
French Polynesia ^a	The Délibération n° 2007–98 APF (2007) regulates activities relating to collection, breeding and repopulation of giant clams
Guam ^a	No commercial harvesting of giant clams allowed under the Fishing Regulations (Cap 12)
India	Of the species inhabiting Indian waters, <i>Hippopus hippopus</i> , <i>Tridacna maxima</i> , and <i>T. squamosa</i> , except <i>T. crocea</i> , are legally protected as Schedule I species under the Wildlife Protection Act of India (1972) (Apte et al., 2010)
Indonesia	Seven species inhabiting Indonesian waters included on the national list of protected species since 1987 under the Surat Keputusan Menteri Kehutanan No. 12/Kpts/II/1987 (Nijman et al., 2015). Now consolidated under the Conservation of Living Resources and their Ecosystems Act, 5/1990, specifically the Government Regulation No. 7/1999 on Preserving Flora and Fauna Species that provides the criteria for specifying protected species (Ezekiel, 2018)
Japan	Prohibits recreational fishing of giant clams under the Okinawa Prefectural Fisheries Regulations. Failing to observe the rules is an infringement of the Japanese Fisheries Law (Okinawa Prefectural Government, n.d.)
Malaysia	Protected under the main Fisheries Act No. 317 (1985), specifically defined by the Fisheries (Control of Endangered Species of Fish) Regulation (1999), where it is an offense to capture giant clams (Ezekiel, 2018). The latter lists four species: <i>Tridacna gigas</i> , <i>T. squamosa</i> , <i>T. maxima</i> , and <i>T. crocea</i> (Gomez, 2015)
Mauritius	Protected under the Fisheries and Marine Resources Act 2007 and it is considered illegal to possess them (Ramah et al., 2018)
Myanmar	The Department of Fisheries Notification for Control of Endangered Fish Species lists protected species, including giant clams (Ezekiel, 2018). It is an offense to capture giant clams as specified in this regulation
New Caledonia ^a	Regulations exist in the Northern and Southern Provinces to manage local harvest of giant clams
Niue ^a	Under the Domestic Fishing Act (1995), gathering of giant clams whose size is less than indicated in the Domestic Fishing Regulations (1996) is not allowed
Palau	Under the Domestic Fishing Laws of Palau (Ref. 27 PNCA 1204), it is against the law to export any of the seven species present in Palau waters, or part thereof, regardless where the species may have originated, except cultured ones (SPC/BMR, 2012)
Papua New Guinea	Managed by National Fisheries Authority under the Fisheries Management Act (1998) and Fisheries Management Regulation (2000) (Yaman, 2009)
Philippines	Protected under The Philippine Fisheries Code of 1998 (Republic Act No. 8550). Under this law, all species listed on CITES (including giant clams) are considered “endangered” and may not be taken without a special permit from the Bureau of Fisheries and Aquatic Resources (Gomez, 2015)
Republic of Kiribati	Management and protection of endangered species under the Fisheries Act, Section 22 and the Environment Act, Section 24 (Kinch and Teitelbaum, 2010)
Samoa	The Fisheries Management Act 2016 prescribes measures for the protection of giant clams (Moorhead, 2018)
Solomon Islands	General management and regulation of giant clam fishery under the Fisheries Act 1998 and the Fisheries Regulation 1998 (Kinch and Teitelbaum, 2010). The latter includes banning the harvesting of wild giant clams for commercial sale
Thailand	Protected under the current Royal Ordinance on Fisheries B.E. 2558 (2015) (previously known as the Fisheries Act 1947) that prohibits fishing of giant clams (Knight et al., 2010). Giant clams given “protected” status under ministerial regulations issued under Section 6 of Wild Animal Reservation and Protection Act No. 3 (2003) (Ezekiel, 2018)
Tonga	Protected under the Fisheries Act 1989, while their harvest is managed under the Fisheries Management Regulation 2008, which prohibits the sale of giant clams in local market without its shells to ensure the clam meets the size limit for each species (Kinch and Teitelbaum, 2010)
Vanuatu ^a	Under the Fisheries Act 2005 (Cap 315), specifically the Fisheries Regulations Order No. 28 (2009), the harvesting of wild giant clams for export is not permitted
Viet Nam	The Ministry of Agriculture and Rural Development Decision No. 82/2008/QĐ-BNN listed three species of giant clams, based on IUCN criteria v2.2 and 2007 Red Book for Viet Nam (Ezekiel, 2018)

^aInformation retrieved from Coastal Fisheries Species Regulations, Management Plans and Legislation in Pacific Island Countries and Territories, SPC Coastal Fisheries Programme. [Online] <http://www.spc.int/CoastalFisheries/CFM/LegalText/ByJurisdiction> (Accessed on 17 December 2018).

Fig. 5 The Bolinao Marine Laboratory, which is part of the University of the Philippines's Marine Science Institute, is one of the longest standing giant clam mariculture programs. The program's focus has been on *Tridacna gigas* (inset), but has bred and farmed other species over the years. The laboratory also runs training courses on handling and culturing giant clams.

Conclusions

Giant clams are endangered in many parts of their geographic distribution. The biggest driver of decline is probably overharvesting for human use (food and materials). Habitat loss, coastal development, pollution and climate change are additional factors that can negatively impact their survival. To highlight the plight of giant clams, conservation measures such as the CITES listings and IUCN Red List of Threatened Species raised awareness of the threats, as well as the enforcement of existing local laws regulates (or bans) both subsistence and commercial fishing. In addition, mariculture and restocking to help maintain population numbers have had some success. Scientific research on giant clams over the years has also helped to reinforce the case for protecting these charismatic molluscs. Moving forward, modern conservation approaches such as biophysical modeling and molecular genetics can help solve basic questions such as larval dispersal and connectivity, fishery projections, and population genetics. Besides science-based conservation and management, it is critical to involve all stakeholders and improve conservation literacy through education, outreach, and capacity building. Highlighting the ecological benefits of giant clams and consequences of overexploitation can help bring about changes in attitude and lead to improved fishing practices.

Abstract

The Coral Triangle encompasses parts of South-East Asia and the Western Pacific and is a priority for marine biodiversity conservation because it has the highest species richness, and endemism, of any marine region globally. Considered to be the region with the world's highest shallow-water reef-building coral species, reef fishes and mangrove biodiversity, this region also comprises important habitats for threatened species. Areas of high biodiversity importance are clustered along the southern part of the Philippines, the north-eastern part of Malaysian Sabah, central to eastern part of Indonesia, the eastern part of Papua New Guinea and the Solomon Islands. Yet, the marine resources in this region are threatened by various human-induced factors and climate change-induced impacts.

Biodiversity Significance of the Coral Triangle Region

The Coral Triangle (CT) region is a marine area situated along the equator between the Indian and the Pacific Oceans. It encompasses parts of South East Asia and Melanesia and includes the Exclusive Economic Zone (EEZ) of six countries: Indonesia, Malaysia, The Philippines, Papua New Guinea, Timor-Leste, and Solomon Islands, as well as the EEZs of two adjacent nations: Brunei Darussalam and Singapore (Fig. 1). This region has been referred to as the "Indo-Malayan Triangle" (Burke et al., 2002), the Indo-Malay-Philippines Archipelago (Carpenter and Springer, 2005), the "East Indies Triangle" (Briggs, 2005), and by many other names reviewed by Hoeksema (2007). Scientists have proposed an ecological boundary of the CT based upon the 500 species isopleth for reef-building coral species richness (e.g., Green and Mous, 2008; Veron et al., 2009).

The Coral Triangle has been known as the global epicenter of shallow marine biodiversity. The main reef types found in the region are fringing, patch, and barrier reefs, with total coverage of 43,577 km² (UNEP-WCMC et al., 2010). In terms of coral diversity, the CT region contains more than 605 zooxanthellate corals, including 15 regional endemics (Veron et al., 2009), with the center of diversity spanning from the Philippines to the eastern part of Indonesia (Hoeksema, 2007). The highest diversity has been found in the Birds Head Seascape of Papua-Indonesia, which hosts up to 577 species of scleractinian corals (Mangubhai et al., 2012). This region also has many deep-sea scleractinian corals with more than 110 species of azooxanthellate scleractinian corals in the deep-water between the Philippines and New Caledonia (Cairns, 2007).

Considered to be the area with the world's highest mangrove biodiversity, 36–46 species out of the world's 70 mangrove species have been found in the region (Polidoro et al., 2010). Of these, 15% have been classified as threatened species. The mangrove forests cover an area of 41,318 km² (Giri et al., 2011a, 2011b) and over 65% of them are distributed in the coastal area of Indonesia (Fig. 2).

Seagrass meadows cover an area of 3263 km² of the CT (Beger et al., 2013). Sixteen out of 60 of the world's seagrass species have been found in the Coral Triangle, mainly on the reef flats (Wilkinson, 2008; Short et al., 2011). The highest diversity was found in the Philippines (14 species), followed by Papua New Guinea and Indonesia (12 species) (Fig. 2) (Green and Short, 2003).

Allen (2008) highlighted that the world's center of reef fish species richness extended from Indonesia to Papua New Guinea and the Solomon Islands, and northward to the Philippines. The Indonesian archipelago contains more than 2122 species of reef fishes (Allen, 2008), and the central Philippines is the world's reef fish epicenter (Carpenter and Springer, 2005). In total, the CT region supports more than 3250 species of reef fishes (Sanciangco et al., 2013) which comprise 52% of Indo-Pacific reef fish (37% of the world's reef fish) (Allen, 2008). The CT is also a center of fish species endemism, with endemism concentrated around Raja Ampat in the Bird's Head Seascape of Indonesian Papua (Fig. 3).

This region also comprises important habitats for threatened species. Six out of seven of the world's sea turtle species inhabit the Coral Triangle's marine and coastal areas as their nesting beaches, feeding grounds, and migratory routes. These turtle species are *Eretmochelys imbricate* (hawksbill), *Dermochelys coriacea* (leatherback), *Chelonia mydas* (green), *Caretta caretta* (loggerhead), *Lepidochelys olivacea* (Olive Ridley), and *Natator depressus* (flatback) (MoF-MoMAF, 2010). The Papuan Beach of Jamursba

Fig. 1 Map of the Coral Triangle, showing Coral Triangle countries EEZ outer boundaries (yellow-dashed line) and distributions of nearly 2000 units of Marine Protected Areas (blue). Country boundaries are indicated by a gray-dashed line.

Fig. 2 Distribution of three biogenic habitat within the Coral Triangle: Coral reefs (red), mangrove forests (green) and seagrass beds (blue). The largest coverage of biogenic habitat was coral reefs followed by mangrove forests and seagrass beds (UNEP-WCMC et al., 2010; UNEP-WCMC and Short FT, 2005; Giri et al., 2011a,b). Adapted from Asaad, I., Lundquist, C. J., Erdmann, M. V., and Costello, M. J. (2018a). Delineating priority areas for marine biodiversity conservation in the Coral Triangle. *Biological Conservation* 222, 198–211. <https://doi.org/10.1016/j.biocon.2018.03.037>.

Medy-Wormon is one of the most significant rookeries for leatherback turtles (Hitipeuw et al., 2007; Mangubhai et al., 2012). It comprises 75% of the total leatherback nesting in the western Pacific and represents the last important nesting population in the entire Pacific (Tapilatu and Tiwari, 2009).

Several species of marine mammals are also found in this region, ranging from cetaceans (whales, dolphins, and porpoises), and sirineans (dugongs). More than 31 species of cetaceans have been found in Indonesian waters (Rudolph et al., 1997). Approximately 15 species have been sighted in the Bird's Head Papua region include Bryde's whales, False killer whales, sperm whales, Indo-Pacific humpback whales, Pan-tropical spotted dolphins and Fraser's dolphins (Kahn, 2007; Mangubhai et al., 2012).

Fig. 3 Distribution of 373 endemic reef fishes within the Coral Triangle. The highest concentration (red) was found in the Raja Ampat Archipelago of Indonesian Papua with over 100 endemic species (Allen and Erdmann, 2013). Adapted from Asaad, I., Lundquist, C. J., Erdmann, M. V., and Costello, M. J. (2018a). Delineating priority areas for marine biodiversity conservation in the Coral Triangle. *Biological Conservation* 222, 198–211. <https://doi.org/10.1016/j.biocon.2018.03.037>.

Areas of Biodiversity Importance

Because the Coral Triangle is the global rich-spot of marine biodiversity, there is a great interest to understand the spatial pattern and distributions of marine biodiversity in the region. Asaad et al. (2018a) identified areas of highest importance for biodiversity protection in the Coral Triangle based on ecological criteria derived from a critical review of international conservation policies (Asaad et al., 2016). The data used for the criteria were: (1) sensitive biogenic habitat was analyzed based on the spatial distribution mangrove forests, seagrass meadows and coral reefs; (2) modeled geographic distributions and occurrence records of species to evaluate the criterion of species richness; (3) distributions of species of special conservation concern; (4) distributions of endemic reef fish species; and (5) distribution of nesting sites and migratory routes of sea turtle species.

Asaad et al. (2018a) found that the areas of the high biodiversity importance (*biodiversity rich spots*) were along the southern part of the Philippines, the north-eastern part of Malaysian Sabah, central to eastern part of Indonesia, the eastern part of Papua New Guinea and the Solomon Islands (Fig. 4). These included seven sites with the richest biodiversity: three sites in the Philippines (i.e., the Verde Island Passage, the southern part of Negros Island and Cebu Island) and four sites in Indonesia (i.e., the northern tip of Sulawesi, Ambon Island, Kei Islands, and Raja Ampat Archipelago) (Fig. 3). These sites contained the full range of biogenic habitat, and were predicted to be inhabited by more 4000 marine species. Three sites (i.e., northern tip of Sulawesi, Kei Island, and the southern part of Negros Island) were also identified as important habitat for three species of sea turtle. The Raja Ampat Archipelago hosted more than 100 species of restricted-range reef fishes, which was the highest number in the Coral Triangle region and probably for all oceans (Fig. 5).

Threats to Biodiversity

The marine resources in the Coral Triangle region are threatened by various indirect and direct human-induced factors including destructive fishing practices, overfishing, pollution and coastal development (Burke et al., 2012; Green et al., 2014). In addition, climate change-induced impacts such as rising sea-level, increasing sea-surface temperature, and ocean acidification are likely to add to these threats (Hoegh-Guldberg et al., 2009; McLeod et al., 2010).

Burke et al. (2012) found that the most destructive threats to the coral reefs in the Coral Triangle region are unsustainable and damaging fishing practices. Indonesia has banned trawling throughout its Exclusive Economic Zone (MoMAF, 2016) and imposed a heavy penalty to the illegal fishing activities. Other destructive fishing methods such as the use of dynamite (blast fishing) and poisonous fishing, although prohibited by law, are still practiced along the coasts of the region (Table 2) (Burke et al., 2012; Bacalso and Wolff, 2014; De Alessi, 2014). In addition, an excess of land-based run-off and sedimentation has led to declines in coral cover, reduced coral diversity, and increased bioerosion along the coasts of Indonesia and the Philippines (Fabricius, 2005).

Fig. 4 Map of clusters of cells of biodiversity importance in the Coral Triangle. Areas of the high biodiversity importance were clustered along the southern part of the Philippines, the north-eastern part of Malaysian Sabah, central to eastern part of Indonesia, the eastern part of Papua New Guinea and the Solomon Islands. Adapted from Asaad, I., Lundquist, C. J., Erdmann, M. V., and Costello, M. J. (2018a). Delineating priority areas for marine biodiversity conservation in the Coral Triangle. *Biological Conservation* 222, 198–211. <https://doi.org/10.1016/j.biocon.2018.03.037>.

Fig. 5 Map showing sites of biodiversity importance in the Coral Triangle. The most significant sites included: (A) Verde Island Passage (between Luzon and Mindoro Island), (B) Negros Island, (C) Cebu Island, (D) Northern tip of Sulawesi, (E) Ambon Island, (F) Kei Islands, and (G) Raja Ampat Archipelago of Indonesian Papua. Adapted from Asaad, I., Lundquist, C. J., Erdmann, M. V., and Costello, M. J. (2018a). Delineating priority areas for marine biodiversity conservation in the Coral Triangle. *Biological Conservation* 222, 198–211. <https://doi.org/10.1016/j.biocon.2018.03.037>.

The Coral Triangle region has also experienced a high rate of mangrove forest loss caused mainly by habitat conversion to aquaculture, human settlements, infrastructure and timber logging (Table 1) (Wilkinson, 2008; Primavera, 2000). In Indonesia, mangrove forests were categorized as 31% in good condition, 27% moderately destroyed and 42% heavily destroyed (Kusmana, 2014).

Large marine species are also experiencing threats of extinction (Polidoro et al., 2008). In the Coral Triangle region, shark fisheries increased during the last decade due to growing demand for shark products, including fins, flesh, oils, and skins (Lack and Sant, 2011; Lack and Sant, 2012).

Table 1 Known threats and impacts to marine biodiversity elements in the Coral Triangle

<i>Habitat and species</i>	<i>Threat</i>	<i>Impact</i>	<i>References</i>
Coral reefs	Anthropogenic (Coral Triangle region)	85% under pressure	Burke et al. (2012)
	Terrestrial run-off (Indonesia)	Reduction of 30%–60% coral diversity	Edinger et al. (1998)
	Blast fishing	Net loss of community equal to US\$ 306,800 per km ² of coral reef	Pet-Soede et al. (1999)
	Coral Bleaching (Tubbataha NP, Philippines, 1998)	22% declined life coral cover	Burke et al. (2012)
Mangrove forests	Conversion to aquaculture ponds, settlements and port developments, harvesting for pulp productions (South East Asia, 1998)	Loss of >50%	Wilkinson (2008)
	Conversion to aquaculture ponds (Philippines, 1950–1998)	Loss of >50%	Primavera (2000)
Seagrass beds	Coastal development	Loss of 30%–60%	Unsworth and Cullen (2010)
	Infrastructure development (Indonesia)	Reduction of >26% seagrass habitat	UNEP (2004)
Sharks	Persistent siltation due to deforestation (Sabah-Malaysia)	Significant decline	Freeman et al. (2008)
	Shark fisheries (Indonesia)	Annual catch = 109,924 t (first world's largest shark harvest)	Lack and Sant (2012)
Sea turtles	Shark fisheries (Malaysia)	Annual catch 23,808 t (10th world's largest shark harvest)	Lack and Sant (2012)
	Fisheries by-catch (Indonesia)	7700 killed every year	Dirhamsyah et al. (2014)
	Legal catch (Papua New Guinea)	> 15,217 turtles per year	Humber et al. (2014)

Further climate change related stressors that may affect marine resources include the raising of sea-surface temperatures. In the year of 1998 (Wilkinson, 2008) and repeatedly in 2010 (Maynard et al., 2012), coral reefs in several locations in this region were severely impacted by mass coral bleaching and mortality events. The severity of bleaching increased between the events in 1998 and 2010 (Heron et al., 2012). In the Philippines, the 1998 coral bleaching was found in the Tubbataha Reef National Park (Table 1) (Burke et al., 2012), while in Indonesia, the 2010 coral reef bleaching was spread-over Indonesian reefs. Severe bleaching was found in the Sumatera and Sulawesi reefs, and minor bleaching was reported in Java, Bali, Moluccas and Papuan reefs (Tun et al., 2010). These bleaching events are become more common, and possibly their frequency is exceeding the time required for recovery in between bleaching events (Heron et al., 2016; Hughes et al., 2018).

Marine Protected Areas

Marine Protected Areas (MPA) have been recognized as the primary mechanism to protect biodiversity and are widely advocated as an effective tool for conserving and managing biodiversity (Brooks, 2010; Costello 2014; Costello and Ballantine, 2015; Venter et al., 2014). MPA have been defined as “a clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve a long-term conservation of nature with associated ecosystem services and cultural values” (Dudley 2008). This broad MPA definition has been applied to various types of MPAs worldwide including MPAs in the CT region. MPAs have been established since the mid-1970s and 1980s in several parts of the Philippines, Malaysia, and Indonesia, followed by Papua New Guinea and Solomon Islands in the late 1990s and Timor Leste in 2007 (Green et al., 2011). They include no-take reserves, sanctuaries, recreation parks, protected landscapes and seascapes, national parks and marine managed areas (Weeks et al., 2014; White et al., 2014). However, contrary to expectations that MPA aim to protect biodiversity in a natural condition, over 90% allow fishing and thus population structures and food webs are altered (Costello and Ballantine, 2015). The Coral Triangle is not exception to this, and thus we consider only <5% of the MPA are fully protected.

Currently, there are 1972 MPA in the Coral Triangle region, covering an area of 200,881 km² (Cros et al., 2014) that are focused on protecting ecological, fisheries, and other essential socioeconomic and cultural values (Table 2) (Walton et al., 2014). Different MPA archetypes are found in different countries (White et al., 2014) due to differences in the science behind the MPA design and the characteristics of social, economic, and governance of each country (Christie and White, 1997; Weeks et al., 2014). Some countries, such as Indonesia, tend to establish large, multiple zone MPAs, while other countries such as the Philippines, Papua New Guinea, and the Solomon Islands prefer to develop small sanctuary areas supported through local government or community-based MPAs (Green et al., 2011; Walton et al., 2014). However, underrepresentation of ecological and biodiversity coverage of marine protected areas occurs in the region, where it was estimated that the current coverage equates to <2% of the Coral Triangle countries EEZ, predominantly located in coastal waters and the average representation of biodiversity features within the existing MPA network was about 5% (Asaad et al., 2018b).

Table 2 The distribution, number, coverage and habitat representation on MPA in the Coral Triangle

Abstract

We distinguish between concepts used to classify and map geographic areas, with examples from the marine environment. Biomes are large areas dominated by long-lived plants providing habitat for other species. Ecosystems are areas where biological interactions and energy fluxes are greater within the area than with adjacent ecosystems. Realms are defined by their geographically rare (endemic) species whereas habitats, communities, whereas biotopes are characterized by the most abundant and/or conspicuous species. While ecosystems and biomes contain guilds of species, they are not defined by them, so their species composition varies geographically. Seascapes, like landscapes, are defined by their physical geography (topography, physiography) alone. However, depth zones are distinguished by environmental conditions, notably light, temperature, oxygen, and nutrients. The term regions is applied to areas with varying ad hoc criteria for their delimitation, including geographic, environmental, biological, and management suitability. Alternative terms for, and examples of, these concepts are provided. Classifications can show relationships within concepts (e.g., habitats, realms) but different concepts (e.g., seascapes and habitats) should not be forced into simple hierarchical systems. The spatial relationships of world realms, biomes, and ecosystems are mapped. Authors are encouraged to apply concepts appropriately and minimize jargon so as not to confuse or alienate readers.

Introduction

This article distinguishes among different concepts used in ecology to classify and map geographic areas, with examples of how they apply to the marine environment (Table 1). It is necessary because terms get loosely used by both scientists and outside ecology, creating confusion into the underlying concepts and about what people are trying to communicate. Many terms are highly context dependent, such as habitat. In some cases, multiple terms apply to the same concept and leave one wondering whether some authors use this jargon to impress readers. Instead, we advocate using the least amount of jargon possible and restricting use to the core concepts reviewed here.

Concepts in ecology may borrow words from vernacular use and contribute words to popular use. For example, the words ecosystems, habitat and ecology are used in socio-political settings. However, the meaning of the word may vary and drift. Habitat is sometimes incorrectly used as an alternative to place, but while every habitat has a place, every place does not have the same habitat. A habitat is not a geographic location. Neither should habitat and ecosystem be used interchangeably, but they often are, even in scientific settings. Another example is where the term endemic in ecology and biogeography refers to a species whose geographic range is limited to a particular area. Popular usage can mean that a species occurs in an area and is not necessarily unique to it, e.g., a disease may be endemic to a country. When people migrate, they move from one place to another, but in ecology, migration means the regular movement of individuals to and from, for example, breeding and feeding grounds. The term substrate is used for the food source that a microbe or enzyme may consume, and has tended to replace the term substratum (plural substrata) used to describe the surface on which an organism lives in or on (but does not necessarily feed on), probably by writers overlooking the subtle difference in spelling and then perpetuating it. However, the context always makes the meaning clear. A glossary of marine ecological terminology has been published as part of this work.

In addition to the different applications of the same words by scientists and the public, some scientists use terms casually, thereby creating or perpetuating confusion in concepts (Jax, 2006; Faber-Langendoen et al., 2020). Here, we distinguish several concepts widely used in ecology to define geographic areas (Table 1). They differ not only in their meaning, but their purpose and how they are measured. These terms are context dependant but not always dependent on the geographic scale. However, several schemes have been proposed to classify regions, seascapes, and habitats based on area (reviewed in Costello, 2009). These use terms like mega-, meso-, macro-, and micro-habitat; or province, region, formation or zone. However, because different schemes apply different scales and units to these terms, such as the variety of definitions of depth zones, it seems better to state the dimensions

Table 1 A summary of the definitions and examples of marine geographic concepts.

<i>Concept</i>	<i>Definition</i>	<i>How measured</i>	<i>Examples</i>
Realm	Geographic area distinguished by a high proportion of endemic species arising from evolutionary history	Geographic distribution of species	Marine realms (Costello et al., 2017, 2018a,b). See Table 3 and Fig. 2
Biome	A large region characterized by similar habitat-forming plant growth forms enduring over years		Kelp forest, mangrove forest, seagrass meadow, salt-marsh, shallow coral reefs
Ecosystem	A large area of similar environmental conditions where it is considered that biological interactions and energy fluxes are greater within the ecosystem than across its boundaries to adjacent ecosystems	Cluster analysis of environmental variables that would define a water mass and be related to ecological conditions, such as nutrients, salinity, light, and temperature	The 3D “Ecological Marine Units” of Sayre et al. (2017a, b.) and the 2D photic zone marine ecosystems (Fig. 2)
Seascape (geoform, hydroform, physiotope)	A topographic or physiographic area defined by the shape of the coastline, bathymetry, and/or hydrography	May be defined visually, by acoustic seabed mapping, aerial photography, spectrophotometric sensing (ocean color), temperature, salinity	Fjord, bay, estuary (if variable salinity), lagoon, banks, straits, sounds, canyon, trench, ridge, shelf, slope, rise, seamount, basin, plain, gyre, upwelling, depth zones (Table 4)
Habitat	A physical environment inhabited by a named species or community over a timescale of years and replicated spatially	Depends on the species or community of interest. The habitat for a marine mammal, seabird, and fish may be very different in size and physical environment	Examples in Table 2 and Fig. 3
Biogenic habitat	A three-dimensional habitat created by a species or group of species, and occurring over a timescale of years and replicated spatially		Biomes at a local scale where the species are named, e.g., <i>Zostera marina</i> meadow. Examples in Table 2, Fig. 3
Assemblage	A group of species found together. Whether they interact or not is not known or assumed		In practice conflated with community
Community (bio-, phyto-, zoo-, micro- coensis)	An assemblage of interacting species in a particular habitat occurring over a timescale of years and replicated spatially	Visual observation, photography, samples of substrata and biota	Examples in Table 2 and Fig. 3
Biotope (ecounit, facies, biofacies)	A combination of a distinct community of species in a defined physical habitat		Examples in Table 2 and Fig. 3.
Ecotones	Boundaries between ecologically defined areas, such as habitats		Pycocline, Thermocline, Sea surface
Region (bio- eco- region, province, zone, section)	Expert opinion and/or based on ad hoc use of biogeographic, oceanographic or management criteria	Variously defined depending on the context of the study. Bioregions may be defined by environmental conditions and selected species distributions	Administrative environmental management areas for fisheries, conservation. Reviewed in Costello (2009) and Zhao and Costello (2019b)

Alternative but less widely used terms, or synonyms, and in parentheses. Keywords are in bold.

of the spatial areas and depth zones than assume a reader knows what is meant by, for example, “deep sea” (Costello and Breyer, 2017; Costello et al., 2018a).

The meaning of terms can also change with usage. For example, the term biotope was first used over 100 years ago to mean the physical habitat of a biocenosis (community) but is now used as the unique combination of a community and habitat (Olenin and Ducrotoy, 2006). The term biotope is useful because different communities may occur the same physical habitat, such as due to successional change and ecological interactions. For example, on rocky habitat, kelp forest replaced “sea urchin barrens” following the restoration of natural food web relationships, called trophic cascades, in a marine reserve (Leleu et al., 2012).

Mapping

Maps are spatial models that illustrate the distribution of environmental features. Their scale and resolution vary, and where areas are mapped, the lines separating them may be more or less a true reflection of natural conditions. Thus, in the present context, the boundaries between areas may be narrower or broader than the lines suggest. The boundaries and areas of marine ecosystems are

relatively stable at low latitudes but vary with seasons in high latitudes, reflecting seasonal changes in temperature, phytoplankton dynamics and nutrient cycles (Zhao and Costello, 2019a). Ecological boundaries separating ecosystems, habitats, and biotopes are termed ecotones (Risser, 1995).

In practice, all spatial units have an implicit size, with realms, biomes, and ecosystems being large, sometimes continental, in area. In contrast habitats, communities and biotopes may occur at scales of centimetres to kilometres. A minimum area of 5 m² is commonly used as a guide for the minimum mapping unit for marine benthos (Costello and Emblow, 2005). Microhabitats within this area, such as rockpools on a seashore, or boulders on a sediment seabed, would be recorded as features of the habitat or biotope as they may significantly affect its species composition and diversity.

Seashores may be also mapped at an entire seashore level based on the dominant substratum and wave exposure conditions, such as achieved for some countries (e.g., Ireland, Neilson and Costello, 1999) and the world (Sayre et al., 2018). The BioMar benthic biotope classification recognizes upper level substratum-based “major habitats” (e.g., Littoral Rock) and second level wave exposure “habitat complexes” within a hierarchical classification (Table 2). The BioMar classification forms the marine component of the European Union Nature Information System (EUNIS) standard classification of habitats for environmental management (Galparsoro et al., 2012).

Biomes are large areas with long-lived plants that provide three-dimensional habitat for other species. The terrestrial biome classification is accordingly primarily based on plant cover and growth forms (Faber-Langendoen et al., 2020). Marine equivalents are mangroves, seagrass meadows, kelp and other seaweed forests, and shallow tropical reef-building corals that host symbiotic algae (Jayatilake and Costello, 2018, 2020). In the absence of true biomes in the open (pelagic) ocean, the term biome has been sometimes used to describe areas defined by satellite derived ocean color indicative of phytoplankton abundance (Reygondeau and Dunn, 2018) and groups of pelagic provinces (Spalding et al., 2012). Other authors may refer to such areas of ocean color as epipelagic ecosystems if they assume biological interactions and energy fluxes are greater within the water mass than with adjacent areas.

A new classification of the terrestrial environment combines layers of vegetation (biomes), with landforms (landscape features), and climate, to create a world map of terrestrial “ecosystems” (Sayre et al., 2020). The same approach is not possible in the oceans because only the ocean fringe has biomes, and most of the ocean seabed lacks plants (Costello et al., 2018a). In contrast, on land, the term habitat usually refers to some form of plant cover.

Areas may also be classified by ad hoc combinations of environmental and biological knowledge, using expert opinion and field observations, and be adjusted to fit administrative needs. Here, we group these under the term regions. Some are management units for countries (e.g., Exclusive Economic Zones), fisheries (Food and Agriculture Organization and International Council for the Exploration of the Sea fisheries management regions), and environmental studies (“Large Marine Ecosystems”) (reviewed in Zhao and Costello, 2019b). Conservation prioritization may define biodiversity hotspots based on their richness of biogenic habitat (e.g., coral reefs), species and endemic species, as conducted for the Coral Triangle by Asaad et al. (2017, 2018, 2020), and for the world ocean (Zhao et al., 2020). However, biodiversity hotspots may also be places with high fish abundance and human impacts (reviewed in Jefferson and Costello, 2020), and the term “hotspots” has been used for areas of high pollution or heat events. Thus the term “regions” is used here to cover the numerous management orientated nomenclature applied to geographic areas in the ocean.

Classification

Because the terms in Table 1 are different concepts they cannot be forced into any linear or hierarchical relationship. Thus, a biome may cross several biogeographic realms (Fig. 1). However, ecosystem boundaries may align with boundaries of biomes and realms because they represent areas with contrasting environmental conditions and these conditions may affect the dispersal of species and hence endemism (Fig. 2). Indeed, all four major marine biomes (Fig. 1) fall within one coastal ecosystem (Fig. 2), and several realm boundaries (only accurate to $\pm 5^\circ$ latitude longitude) approximately align with ecosystem boundaries (e.g., Southern Ocean).

Classifications are our attempt to organize concepts. They can have predictive value when one level in a classification is known to be regularly associated with its neighbors and other levels. For example, species classifications inform how one species is related to others. However, the true relationships between the geographic concepts in Table 1 are more likely to be multi-dimensional than linear. Nevertheless, it can thus be informative to show how habitats and communities form biotopes in a two-dimensional matrix (Fig. 3). When concepts are independent it does not necessarily help to force them into hierarchical relationships, some with 10 levels in the hierarchy (e.g., Last et al., 2010).

Any classification of habitats invariably must make some arbitrary decisions which means it is likely to differ from classifications developed for other geographic regions and environments. A physical habitat may occur in several ecosystems, seascapes, or realms; such as a wave exposed rocky seashore. Thus, to try to form a hierarchical relationship (for example) of habitats within seascapes is misleading because it may suggest a habitat may only occur within that seascape whereas it may occur in several (Costello, 2009). Instead, habitats and seascapes, like biomes and realms, should be mapped and reported separately as they are different concepts; neither is a subset nor superset of another.

The basic units of habitat classifications as observed in the field can be reconciled between studies, enabling comparison of maps of habitats and biotopes across decades (Leleu et al., 2012; Remy-Zephir et al., 2012). In addition, methods of assigning certainty to marine benthic habitat maps developed in Europe can be applied internationally, including in New Zealand (Lee et al., 2015).

Table 2 A checklist of the upper three levels (major habitat, habitat complex, biotope complex) of the BioMar marine biotope classification of Connor et al. (1997a,b) illustrated in two-dimensions in Fig. 3.

<i>Littoral rock</i>	<i>Cirralittoral rock</i>
Lichens or algal crusts (9)	Exposed
Exposed (mussel/barnacle shores)	Faunal crusts or short turfs (3)
<i>Mytilus</i> (mussels) and barnacles (7)	<i>Alcyonium</i> -dominated communities (tide-swept/vertical) (4)
Robust fucoids and red seaweeds (3)	Barnacle, cushion sponge and Tubularia communities (very tide-swept/sheltered) (5)
Moderately exposed (barnacle/fucoid shores)	Moderately exposed mixed faunal turfs (4)
Barnacles and fucoids (7)	Bryozoan/hydroid turfs (sand-influenced) (9)
Red seaweeds (5)	Cirralittoral <i>Sabellaria</i> reefs (1)
Ephemeral green or red seaweeds (freshwater or sand-influenced) (3)	Mussel beds (open coast cirralittoral rock mixed substrata) (3)
<i>Mytilus</i> (mussels) and fucoids (3)	Brittlestar beds (2)
<i>Sabellaria</i> (honeycomb worm) reefs (1)	Grazed fauna (moderately exposed or sheltered rock) (2)
Sheltered (fucoid shores)	Ascidian communities (silt-influenced) (3)
Dense fucoids (stable rock) (10)	Soft rock communities (2)
Fucoids, barnacles or ephemeral seaweeds (mixed substrata) (8)	Sheltered
<i>Mytilus</i> (mussel) beds (mixed substrata) (1)	Brachiopod and solitary ascidian communities (8)
Rockpools (9)	Sheltered <i>Modiolus</i> (horse-mussel) beds (2)
Overhangs and caves (3)	Faunal turfs (deep vertical rock) (2)
	Caves and overhangs (deep) (1)
<i>Littoral sediments</i>	<i>Cirralittoral offshore rock</i>
Littoral gravels and sands	<i>Lophelia</i> (cold-water coral) reefs (1)
Shingle (pebble) and gravel shores (2)	
Sand shores (7)	<i>Sublittoral sediments</i>
Estuarine coarse sediment shores (1)	Infralittoral gravels and sands
Littoral muddy sands	Maerl beds (open coast/clean sediments) (4)
Muddy sand shores (4)	Shallow gravel faunal communities (2)
Littoral <i>Zostera</i> (seagrass) beds (1)	Shallow sand faunal communities (5)
Littoral muds	Estuarine sublittoral gravels and sands (3)
Saltmarsh (26 +)	Cirralittoral gravels and sands (3)
Sandy mud shores (4)	Infralittoral muddy sands
Soft mud shores (3)	Seagrass beds (2)
Littoral mixed sediments (2)	Shallow muddy sand faunal communities (4)
	Cirralittoral muddy sands (5)
<i>Infralittoral rock</i>	Infralittoral muds
Exposed	Angiosperm communities (lagoons) (2)
Kelp with cushion fauna, foliose red seaweeds or coralline crusts (13)	Shallow marine mud communities (4)
Robust faunal cushions and crusts (surge gullies & caves) (10)	Estuarine sublittoral muds (7)
Moderately exposed	Cirralittoral muds (3)
Kelp with red seaweeds (11)	Infralittoral mixed sediments
Grazed kelp with algal crusts (3)	<i>Laminaria saccharina</i> (sugar kelp) and filamentous seaweeds (4)
Sand or gravel-affected or disturbed kelp and seaweed communities (7)	Maerl beds (muddy mixed sediments) (3)
Sheltered	Oyster beds (1)
Silted kelp (stable rock) (14)	Shallow mixed sediment faunal communities (3)
Estuarine faunal communities (shallow rock/mixed substrata) (3)	Estuarine sublittoral mixed sediments (3)
Submerged fucoids, green and red seaweeds (lagoonal rock) (4)	Cirralittoral mixed sediments (3)
Other fauna and seaweeds (shallow vertical rock) (3)	Cirralittoral offshore sediments (3)

The species on rock may also occur on other hard substrata (e.g. shells, piers, and shipwrecks). The number of biotopes and sub-biotopes described in Connor et al. (1997a,b) is indicated in parentheses.

A common area of confusion is where ecosystems, seascapes, and habitats are conflated because all comprise a geographic area with distinct environmental conditions and are inhabited by some species. While species occur in ecosystems, they do not define them. In contrast, species composition defines a habitat. Seascapes are agnostic to what species occur within their area. For example, there are about 70,000 seamounts (submerged mountains more than 1 km high from the seabed), and over one million sea-hills (Costello et al., 2010). A seamount is a seascape defined by the seabed topography, and it may be a habitat for some large mobile species, like a bay may be a habitat for mammals or birds. However, it will contain a variety of habitats for benthic species depending on depth, substrata, wave and current exposures, and the same habitats will occur elsewhere. The seamount may even form a distinct oceanographic ecosystem due to its effects on water movements and the pelagic-benthic interactions, as suggested by

Fig. 1 World maps showing how one biome (in red), seagrass, is distributed across all except the polar realms (Table 3) (Jayatilake and Costello, 2018, 2020). Two biomes, mangroves and shallow reef-building corals, are limited to tropical and sub-tropical realms, while the fourth, laminarian kelp biome is distributed in cold temperate high latitudes (Jayatilake and Costello, 2020). The areas occupied are 1,646,788 km² for seagrass, 1,469,900 km² for laminarian kelp, 151,390 km² for shallow water corals, and 136,850 km² for mangroves. Each biome consists of tens of species, but varying species composition in each realm.

Fig. 2 The Zhao epipelagic marine ecosystems of the world (Zhao and Costello, 2019a,b; Zhao et al., 2019) overlaid by the boundaries of the biogeographic realms. Note the biomes (Fig. 1) occur in the coastal ecosystem which is most visible around continents, and also in small coastal ecosystems around oceanic islands which are difficult to see due to the map resolution.

some of the distinct ecosystems around ocean islands (Zhao et al., 2019). In fact, the mapping of seascapes is more the domain of physical geography than ecology, and regional and global maps of seabed geomorphological units have been published (e.g., Greene et al., 1999; Heap and Harris, 2008; Harris and Whiteway, 2009; Last et al., 2010; Harris et al., 2014). Specialist classifications of coastal seascapes based on tides and salinity (Tagliapietra et al., 2009) and sediments (Boyd et al., 1992) have also been proposed. While seascapes are analogous to landscapes on land, they may also be physically defined by water body conditions and termed pelagic seascapes (Kavanaugh et al., 2016).

Substratum → Zonation ↓ Wave exposure →	ROCK			Mixed sediment	SEDIMENT		
	Exposed	Moderate	Sheltered		Gravel, Coarse sand	Sand, fine to medium	Mud (> 30 % silt)
Littoral	Lichens				SALT MARSH		
	Ephemeral green & red seaweeds (low salinity)			Gammaridae (low salinity)	Barren		
	Barnacles & <i>Mytilus</i> (mussel)	<i>Fucus</i> , limpet, barnacles	<i>Ascophyllum</i>	Sugar kelp & filamentous seaweeds	Burrowing amphipods, bivalves rare	Polychaetes & bivalves, burrowing amphipods rare	Polychaetes, <i>Corophium</i> , <i>Hydrobia</i>
	Red seaweeds & <i>Corallina</i>	<i>Sabellaria</i> reefs	Mussel beds				
Sub-littoral	Sponges & bryozoa under kelp	Grazed rock under kelp	Silted under kelp	Submerged fucoids	<i>Zostera</i> spp.		
	anemones, sponges & colonial ascidians (wave surge tolerant)		fauna		Maerl		
	coralline algae & calcareous tubeworms (scour tolerant)	Brittlestar beds	Modiolus (mussel) beds			Burrowing megafauna <i>Nephrops</i> ,	
			Serpulid (tube-worm) reefs	Hydroid-bryozoan (current swept)	<i>Amphura</i> spp. polychaetes	seapens	
	<i>Flustra</i> , hydroids, <i>Alcyonium</i> (current tolerant)	<i>Sabellaria</i> reefs Rich faunal turfs	Axinellid sponges & brachiopods	Solitary ascidians (silt tolerant)	<i>Neopentadactyla</i> , <i>Venerupidae</i>	<i>Abra</i> , <i>Nucula</i> , <i>Corbula</i> , spionid polychaetes	<i>Beggiatoa</i>

Fig. 3 Example of a marine seabed biotope matrix showing the spatial relationships between the communities (colored boxes) and their physical habitat defined by height (intertidal = littoral), depth (subtidal = sublittoral), substratum and wave exposure for benthos in Irish and British seas. These factors distinguish biotopes at the upper levels of the European marine biotope classification developed by the BioMar project (Table 2). Within the matrix the characteristic species of the communities occurring in the habitats are indicated (see classification for full definitions and details). Based on Costello MJ, Emblow, C (2005) A classification of inshore marine biotopes. In: Wilson JG (ed.) *The Intertidal Ecosystem: The Value of Ireland's Shores*. pp. 25–35. Dublin: Royal Irish Academy.

In contrast to habitats, ecosystems are usually considered over larger areas. What makes the concept of ecosystem unique is that it is a geographic area where ecological exchange of energy and matter is stronger within than across a boundary to adjacent ecosystems. This is difficult to measure but can be approximated by measures of temperature and biologically influenced variables (e.g., nitrogen, phosphorous, silicate, oxygen) as conducted for the world ocean by Sayre et al. (2017a,b), Costello et al. (2018a,b) and Zhao et al. (2019) (reviewed in Zhao and Costello, 2019a,b), and increasingly available at global scales (e.g., Basher and Costello, 2019; Basher et al., 2020).

The concept of coral reef ecosystems is widely applied to shallow subtropical areas that include coral reefs. They include varying areas of sandy and rocky habitats, and seagrass meadows. Whether coral reefs form truly closed ecosystems is doubtful but yet the term is useful because “coral reefs” alone may only refer to the living corals which are a small part of a reef “ecosystem” (Hatcher, 1997). Similarly, the same corals can extend into deeper water where they are called mesophotic corals (Laverick and Rogers, 2020). These are sometimes called mesophotic coral ecosystems, although habitats or biotopes may be more appropriate (Tables 2–4).

Species Guilds and Traits

In addition to terms used to map geographic areas, ecological guilds are groups of species that are similar in size and role in an ecosystem (Costello, 2009). For example, the pelagos and benthos refer to organisms living in open water and associated with the seabed respectively. The first can be subdivided by whether they live on the ocean surface (pleuston), in the tens of centimetres under the surface (neuston), are too small to control their horizontal distribution (plankton, although they may adjust their depth), are large and swim effectively against the current (nekton), or are animals (e.g., zooplankton) or plants (e.g., phytoplankton). Benthic guilds may live within the seabed (infauna), upon the seabed (epibiota, epifauna, epiflora), in the water above but associated with the seabed (i.e., demersal = hyperbenthos = benthopelagic), and interstitially nested within epibiota or sediments (Costello et al., 2020).

Guilds may also be distinguished by body size, or as a consequence of the net or sieve used to sample or process samples. The terms macro- and meio- benthos, pico- and nano-plankton, and mega-fauna are common in marine ecology, but intermediate micro- and meso- size groups are also used (Costello et al., 2015, 2016, 2020).

Taxa may also be grouped into groups based on their diet and comprise: predator, scavenger, omnivore, herbivore, parasite, plant (photoautotroph), grazer, suspension feeder, filter feeder, deposit feeder, detritivore, decomposer, and chemoautotroph. In addition, taxa may be grouped by their “habit”: sessile, sedentary, tubicolous, burrowing, drifting, solitary, gregarious, social, colonial, encrusting, inquiline, symbiotic, mobile (vagile), and natant (swimming). For definitions of these and other ecological terminology see Costello et al. (2020). These attributes may also be considered as species traits (Costello et al., 2015).

Table 3 The marine biogeographic realms (Fig. 2).

Realm level 1	Sub-realm level 2	Sub-realm level 3	Realm
Inner Baltic Sea			1
Black Sea			2
NE & NW Atlantic & Mediterranean, Arctic & North Pacific	NE Atlantic & Mediterranean	NE Atlantic	3
		Arctic Europe	4
		Mediterranean	5
	Arctic & N Pacific	Arctic	6
		North Pacific	7
		N Atlantic boreal & sub-Arctic from Canada to Greenland Sea	8
Mid-tropical North Pacific Ocean			9
South-east Pacific			10
Mid-Atlantic, Pacific & Indian Oceans including coastal tropics & warm-temperate areas	Tropical W Atlantic & Tropical E Pacific	Tropical W Atlantic	11
		Tropical E Pacific	12
	Coastal Indian Ocean, W Pacific, Arabian Gulf to New Caledonia, S Pacific tropical islands, & N, W & E Australia.	Tropical Indo-Pacific & coastal Indian Ocean	13
		Red Sea	14
		Tasman Sea to SW Pacific	15
		Tropical Australia & Coral Sea	16
	Open Atlantic, Indian, & Pacific oceans	Mid South Tropical Pacific	17
		Offshore & NW North Atlantic	18
		Offshore Indian Ocean	19
		Offshore W Pacific	20
		Offshore S Atlantic	21
		Offshore mid-E Pacific	22
		Tropical E Atlantic	23
	S South America	Argentina	24
		Chile	25
	S Africa, S Australia, & New Zealand	S Australia	26
		S Africa	27
		New Zealand	28
North West Pacific			29
Southern Ocean			30

The classification hierarchy is based on overlap in species composition. Note the Inner Baltic and Black Seas were distinct because they included freshwater species and may thus not be considered as marine as the other realms. N = north, S = south, E = east, W = west.

Following Costello MJ, Tsai P, Wong PS, Cheung A, Basher Z, Chaudhary C (2017) Marine biogeographic realms and species endemism. *Nature Communications* 8(1057).

Table 4 Depth zones and associated nomenclature in the ocean.

Depth (m)	Environment	Pelagos	Benthos	Ecosystem function
0	Tidal air exposure	Epipelagic (phytoplankton)	Littoral	Photosynthesis and respiration. Variable nutrients and oxygen.
200	Photic zone		Infralittoral (seaweeds)	
1000	Twilight zone < 1% light	Mesopelagic	Circalittoral	
2000	Aphotic zone < 4 °C	Bathypelagic	Deep-sea	Respiration low. Higher nutrients. Low oxygen.
4000		Abyssopelagic Hadopelagic	Abyss	

Changes in the air and light exposure of the environment with depth are reflected in changes in dominance of plants in both the pelagos (the water-column biota, including phytoplankton) and benthos (the seabed biota including seaweeds, seagrass, and corals with symbiotic microalgae). These biota then determine the ecosystem function, including concentrations of oxygen, carbon dioxide and available nutrients. Environmental variability declines with depth, and there are no "Ecological Marine Units" unique to depths below 4000 m (Costello et al., 2018a,b).

Adapted from Costello MJ, Breyer S (2017) Ocean depths: The mesopelagic and implications for global warming. *Current Biology* 27(1): R36–R38. 10.1016/j.cub.2016.11.042.

Conclusions

The concepts reviewed here are useful for understanding how biodiversity exists where it does, and how it functions. Realms reflect past evolutionary conditions, including continental drift. The geographic distributions of ecosystems and biomes reflect current environmental and ecological conditions over large areas, while habitats, communities, and biotopes reflect local conditions. Realms are defined by the presence of geographically rare endemic species whereas habitats and communities are defined by the most abundant or otherwise dominant species. Seascapes are defined by physiography and not biology, while ecosystems are defined by ecological interactions and energy fluxes, not particular species. Consistent and accurate uses of these concepts will improve the clarity of scientific communication.

Abstract

Although marine parasites are often small cryptic organisms that are difficult to study, they are a highly adapted, diverse group of organisms playing important roles within ecosystems. Parasites have complex lifecycles that involve a single host or a number of intermediate hosts. Parasites have been shown to act as ecosystem engineers, sometimes changing the behaviour of one host in order to enable their transition to the next host. The many modifications that individual parasites make have implications for the structure of food webs and the functioning of ecosystems. Their ubiquitous presence can be used to understand the structure of and pressures on host species and food webs. While it is tempting to assume that parasites have similar biogeographic patterns as their hosts, studies have shown that external parasites have different spatial distribution trends, trends which have implications with regards to climate change. Although marine species are generally expected to decline as climate change increases, current research indicates that climate change may be favorable for parasite pathogenicity and distribution. This could have economic impacts on fisheries and aquaculture and biological impacts on the function and structure of marine ecosystems. This article reviews our current biological and ecological knowledge of parasites, discusses how parasites have been used as a tool to understand other aspects of the marine realm, and outlines current predictions regarding the response of parasites to climate change.

Introduction

Parasitic organisms are typically small cryptic animals concealed on or within their hosts and are often noticed only when their presence causes pathogenicity (illness) in commercially relevant species or pets. In addition to the direct effects they cause to their hosts, ecologists are discovering the indirect roles that parasites play in structuring the marine environment. This article introduces the diversity of marine parasites, the interactions with their hosts, and the consequent effects they have on marine food webs and ecosystems.

Defining Parasites

Definitions of what constitutes a parasite vary from field to field. The study of parasites is approached from a number of disciplines, including physiology, ecology, epidemiology, veterinary, economics and evolutionary biology. For this article, parasitism is understood to be a close association of two organisms, in which one (the parasite), during at least one life-history stage, depends on the other (the host) and directly derives some nourishment and/or shelter from it but does not intentionally kill the host. The direct benefit to the parasite is almost always in the form of food, but other benefits have been noted including habitat, shelter and transport. Microbiologists have focussed on fungi, viruses and bacteria and have considered some of these as parasitic, but for the purposes of this article, we will only consider animal parasites which infest other animals (see Table 1 for specific taxa). Specifically,

Table 1 Major groups of metazoan taxa where parasitism has transitioned, the predicted number of these transitions and the number of extant parasitic species within these taxa

Updated and adapted from Poulin, R. and Morand, S. (2004) *Parasite Biodiversity*. Washington, DC: Smithsonian Institution Press; Blaxter, M. and Koutsovolous, G. (2014). The evolution of parasitism in Nematoda. *Parasitology* **142**, S26–S39. doi: 10.1017/S0031182014000791; Costello, M.J. (2016). Parasite rates of discovery, global species richness and host specificity, *Integrative and Comparative Biology* **56**(4), pp. 1–12. DOI: 10.1093/icb/icw084; Weinstein, S. B. and Kuris, A. M. (2016). Independent origins of parasitism in Animalia, *Biology Letters* **12**, p. 20160324. DOI: 10.1098/rsbl.2016.0324. Parasite numbers synthesized from Catalog of Life (Roskov, Y., et al. (2018). *Species 2000 & ITIS Catalogue of Life, 2018 Annual Checklist. Species 2000: Naturalis*. The Netherlands: Leiden. ISSN 2405-884X: Digital resource at www.catalogueoflife.org/annual-checklist/2018.) and Global Biodiversity Information Framework (GBIF) Backbone Taxonomy (GBIF: The Global Biodiversity Information Facility. (2019). *What is GBIF?*. Available from <https://www.gbif.org/what-is-gbif>).

we exclude animals that feed off plants, such as the many species of plant-feeding insects and roundworms, as these are considered herbivores, and we exclude parasitoid insects because they intentionally kill their host and are therefore considered predators (Costello, 2016; Lucius and Poulin, 2017).

Parasite Diversity

Parasitism has evolved at least 223 times in 15 of 35 recognized animal phyla (Weinstein and Kuris, 2016). It is believed that parasitism evolved through a variety of opportunistic circumstances: from using larger animals for food, shelter, increasing dispersal potential, and maintaining more consistent environmental conditions by living in close proximity (Poulin and Morand, 2004). There are also cases of parasites that are closely related to their hosts—even within the same species. For example, ceratoid angler fish have adopted parasitism to solve the problem of reproduction in the darkness of the ocean depths. In some species, once the male locates the female, he latches on to her and eventually fuses to her, providing sperm to fertilize her eggs. As he is then permanently attached, he derives nutrients from the female (Pietsch, 2005).

Hosts may have one to many species of parasites. For example, *Thyrstites atun*, a predatory species of snake mackerel that occurs in the southern hemisphere, has been found to host 16 species of parasites (Nunkoo et al., 2016). Such data have led researchers to the conclusion that there are more parasitic species than host species (Toft, 1986; Poulin, 2014). Even so, of all described animal species, it is estimated that only 5% are parasitic (Costello, 2016). There have been many discussions about why there is this lack of described parasitic species, particularly referencing; their cryptic lifestyle and the difficulty in locating and identifying parasitic species; the lack of research in large geographic regions, for example, the deep ocean; the predicted hyper diversity; a paucity of parasite taxonomists; the use of as yet unrecognized synonyms; and under-sampling even within well studied taxa (e.g., birds and elasmobranchs) (Rohde, 2002; Caira and Jensen, 2014; Chaudhary et al., 2016; Poulin and Presswell, 2016; Jorge and Poulin, 2018).

With the introduction of data-centred science (Kelling et al., 2009) and a renewed effort to determine how many species there are in the world, analyses by some researchers have concluded that most species on earth have been named (Costello et al., 2012, 2013a; Costello and Chaudhary, 2017). Costello et al. (2015) analyzed the trends in rates of description for 32,000 fish species globally. They discovered that the species to be first described tended to be more widespread and larger in size and occurred in shallower depths and near more developed countries (e.g., northern hemisphere). In analyzing trends in rates of description for parasites in both marine and terrestrial ecosystems, Costello (2016) found that most molluscs, crustaceans, ticks, fleas, and insects had decreasing rates of description since the year 2000, with the peak discovery period for helminths and microsporidians occurring in the 1970s. This suggests that most parasites have been named and that further surveys for parasitic diversity will demonstrate that parasitic species discoveries may not yield as many species as non-parasitic taxa (Costello, 2016), challenging current predictions (Poulin, 2014).

Adaptations to the Parasitic Lifestyle

Parasites have evolved complex defensive strategies and developed intricate life cycles to improve their survival. Some parasites have developed simple or direct life cycles that involve active transmission via free living larval stages that attach to passing hosts (e.g., Rhizocephala, Ascothoracica, Copepoda, and Monogenea). For example, parasites of the class Monogenea have adapted to living on the skin, fins and gill filaments of fresh water and marine fish (Rohde, 2005). The hermaphroditic adults release eggs into the water column. When the eggs hatch, they release a heavily ciliated larval stage known as an oncomiracidium. These oncomiracidium have numerous posterior hooks and opportunistically latch onto passing hosts, completing their lifecycle. The larval hooks develop into complex holdfast organs or “haptors,” which are specifically adapted to maintain attachment to their preferred host (see Fig. 1 for examples).

Fig. 1 Showing haptors of *Callorhynchicola multitesticulatus* and *Callorhynchicotyle callorhynchi* found infecting gill filaments of *Callorhinchus capensis* in South Africa (40x magnification). (Photo's by TM).

In contrast to the simple and direct life cycle of Monogenea, other parasites have developed complex or indirect lifecycles where sexual reproduction occurs in the definitive host and various stages of development and/or asexual reproduction occur in one or more intermediate hosts (e.g., Cestoda, Trematoda, Acanthocephala, Nematoda) (Table 2). For example, *Curtuteria australis*, a digenean trematode off the New Zealand coast (Allison, 1979; Fig. 2) has two intermediate hosts. Its eggs are released in the droppings of oystercatchers (*Haematopus* spp.), its definitive host. These eggs are ingested by the whelk *Cominella glandiformis*, a marine gastropod snail, where they develop into larvae (called redia) in the digestive gland. Once temperatures reach 20°C, the redia release free swimming larvae (called cercaria) into the surrounding water, which infect the cockle *Austrovenus stutchburyi*. In heavily infected cockles, not only is foot tissue replaced by the metacercaria cysts, but the size of the foot relative to that of the shell is reduced, leading to the diminished ability of the cockle to bury itself in the sand (Thomas and Poulin, 1998). This alteration in behaviour makes the cockle seven times more susceptible to predation by shorebirds (Thomas and Poulin, 1998). Once consumed by the oystercatcher, the parasite infects the digestive tract, completing its life cycle.

Whether their lifecycles are simple or complex, parasites in both categories have evolved the ability to infect a range of potential micro habitats that the host's body may provide. Like the monogenean example above, parasites can infect specific regions of their hosts, including musculature, various organs and cavities and externally in gill chambers, fins, mouth, skin, and scales. The traits parasites have developed to survive these micro habitats include: a reduction in size compared to related non-parasitic species; a reduction or complete loss of sensory and/or locomotory structures; the development of attachment organs so as not to be carried away or cleaned from the host; resistance to host immune systems and/or protection against hostile environments (e.g., cuticles); and specialized reproductive strategies with high reproductive potential.

Parasite-Host Coevolution

Due to the antagonistic nature of the host-parasite interaction, unique selection pressures are exerted on both the parasite and the host, resulting in parasites that are highly specialized to infect particular hosts. However, there are exceptions, like trypanorhynch cestodes that can infect multiple intermediate host species. This parasite-host interaction creates an evolutionary tension that allows for a delicate equilibrium to be created between the host and the parasite (Hudson, 2005). This evolutionary equilibrium is known as the Red Queen Hypothesis; namely that both parasite and host must continuously adapt to keep up with each other's adaptations (Morand and Krasnov, 2010). However, creating a defensive strategy against every potential parasitic species would be a costly endeavor for the host. Therefore, it is less costly to allow a moderate level of defense at the expense of slight infection. For a parasite, it is worth having a lower level of pathogenicity within a host, so as to not activate the host's full defenses which allows for improved transmission. It is within these moves and counter moves that we get a glimpse of just how parasites may structure entire ecosystems through their effects on host abundance and/or behaviour.

Ecology of Parasites

Effects of Parasites on Ecosystems

If we continue with the example of *Curtuteria australis*, this parasite controls how energy is transferred through the ecosystem by directly effecting predator-prey interactions. This is done by limiting the natural behaviour of the whelk to a riskier behaviour. This small change alters the food web dynamics and community structure in the ecosystem. A parasite's impact on reducing host fitness and modifying competitive and trophic interactions among species have effects on the abundance of different species and the strength of interactions between them. Therefore, the parasite impacts the way that energy flows through the ecosystem directly.

Table 2 Parasitic taxa of marine organisms, their type of life cycle, mode of transmission to the next host and general habitat on host

Main parasitic taxa	Direct/indirect life cycle	Mode of transmission	Habitat
<i>Crustaceans</i>			
Branchiura	Direct	Active—Attachment	External—body surface
Copepoda	Direct and indirect	Active—Attachment	External—body surface, oral cavity, eye
Ascothoracida	Direct	Active—Attachment	External—anchored within and on body surface
Rhizocephala	Direct	Active—Attachment	External—body surface
Thoracica	Direct	Active—Attachment	External—body surface
Amphipoda	Direct	Active—Attachment	External—body surface
Isopoda	Direct	Active—Attachment	External—body surface, oral cavity
<i>Helminths</i>			
Acanthocephala	Indirect	Passive—Ingestion	Internal—gut
Cestoda	Direct and indirect	Passive—Ingestion	Internal—body cavity, gut
Monogenea	Direct	Active—Attachment	External—body surface, gills, oral cavity
Nematoda	Indirect	Passive—Ingestion	Internal—body cavity, gut
Trematoda	Direct and Indirect	Active and Passive—penetration or ingestion	Internal—gut and many internal organs

Within the marine realm, one of the clearest and well documented geographic patterns is the latitudinal diversity gradient (Hillebrand, 2004). Latitude is a surrogate for temperature and solar radiation (including day length and seasonality), which in turn influences primary and secondary productivity (Chaudhary et al., 2016). Chaudhary et al. (2016, 2017) reviewed the literature and available global data for 65,000 marine species and concluded that species diversity increased with decreasing latitude. This

translates to a diversity gradient with low levels of diversity at the poles and a gradual increase through the temperate zone toward the tropics.

This increase in diversity is observed in internal parasites, particularly helminths of marine fish (Rohde, 2002, 2010, 2016; Jorge and Poulin, 2018). Jorge and Poulin (2018) tested the expected spatial similarity between host and parasite diversity for helminth parasites of vertebrate hosts across the globe, including marine fish. Their results show that although associations were weak, there was a significant positive covariation between host species richness and the number of parasite species reported in the same latitude, supporting the observed latitudinal trends for endo parasites. These results show that as host diversity increases, there is a similar increase in endoparasitic diversity.

Ectoparasites, however, amplify this latitudinal gradient and show an increase in relative diversity compared to their endoparasitic counterparts, with comparatively higher species diversity of monogenean flukes per species diversity of hosts, as latitude decreases (Rohde, 2002, 2016). The most likely explanation, according to Rohde (2002), for this relative increase in ectoparasitic diversity compared to other parasitic species is due to temperature. Decreasing latitude results in a general increase in temperature and genetic studies have shown that with increasing relative temperature, there is an increase in evolutionary speciation rates in plants and animals (Rohde, 2002; Gillman et al., 2014).

Longitudinal gradients

Longitudinal gradients of diversity have not been as well documented as latitudinal gradients, but centres for high diversity compared to other areas around the globe have been recorded (Morand and Krasnov, 2010). A primary area is within the Coral Triangle of the Western Pacific Ocean (Asaad et al., 2019). A secondary area is the Caribbean, although this area is not as diverse as the Coral Triangle (Rohde, 2010).

It has become clear that there are barriers to longitudinal dispersal in the oceans, which inhibit the movement of species across the globe. The most effective barrier appears to be the Eastern Pacific Barrier which, due to a lack of islands and a deepening of the thermocline toward the east, reduces the dispersal potential of many species, including parasites, from the western to the eastern parts of the Pacific (Morand and Krasnov, 2010). The “New World Barrier,” represented by the North and South American continents, prevents longitudinal species movement between the eastern Pacific and the Atlantic (Costello et al., 2017). These phenomena have been documented for monogenean and copepod parasites of tuna and mackerel species (Rohde and Hayward, 2000).

Depth gradients

Reviews of marine diversity show an exponential decrease in diversity with depth with a suggested peak at approximately 400–500 m (Costello and Chaudhary, 2017). Rohde (1984) reviewed data of vertical gradients for parasitic species from several authors and concluded that parasite diversity and prevalence becomes poorer with depth. Inshore and open ocean surface fishes have more species of parasite and a greater abundance of parasites than midwater species (Marcogliese, 2002). However, bottom dwelling (benthic) fishes had more species and greater numbers of parasites than midwater (pelagic) species. This is probably due to their food including more infected intermediate hosts, being larger in body size and with a longer life span than mid water species (Rohde, 2010).

There is little knowledge of parasites of the deep oceans. The deep ocean (depths deeper than the continental margin, approximately 200 m) is a hostile environment with low temperatures (2°C average), no light penetration which makes photosynthesis practically impossible and a food supply that is dependent on detritus from the upper levels of the ocean (Costello and Breyer, 2017). This environment is not conducive to high diversity. However, there are exceptions, particularly around hydrothermal vents, whale falls and cold seeps that have an incredible abundance of animals for such hostile environments. Whether parasite abundance is also high in these habitats remains to be studied (De Buron and Morand, 2004).

The latitudinal, longitudinal and depth gradients in marine parasites remain to be analyzed at global scales and across all marine parasite taxa. At present it appears they follow the same biogeographic patterns as other species, but confirmation across a broader scale is desirable. Furthermore, the species richness and endemism of parasites and their hosts are not necessarily linearly correlated. For example, there may be thresholds of host population density where parasites become more or less pathogenic due to dispersal success.

Societal Importance of Marine Parasites

Humanity’s dependence on the ocean for food and ecosystem services is well documented. Almost 80% of commercially relevant marine species are being fully exploited or over exploited (FAO, 2016). As a result, the 21st century has seen unprecedented developments of aquaculture initiatives, currently contributing over 40% of total marine resources for human consumption (FAO, 2016). With humankind’s dependence on these resources in mind and the established knowledge of how ingrained parasitic organisms are within these ecosystems, we’ll discuss how marine parasites impact human society. We consider this impact both directly, in the sense of infection, and indirectly, in their impact that is of commercial relevance.

Public Health

Most parasitic organisms infect the portions of the fish that humans don't eat, particularly the visceral organs that are removed before consumption. There are parasitic organisms that infect the flesh of fish (usually intermediate stages of helminth parasites), and of these, only a few have health impacts on humans. Fortunately, most of these parasites are killed after cooking for 1 min at 60°C or frozen to -20°C for 24 h (Olsen, 1986). However, with the increasing popularity of consuming raw, smoked and/or undercooked fish, the occurrence of human infections from this source has increased (Olsen, 1986; Macpherson, 2005). Parasite infection from raw marine fish involves only two kinds of helminth parasites; from the *Anisakidae* family (e.g., round worms, Nematoda) and the *Diphylllobothrium* genus (e.g., tape worms, Cestoda).

Anisakid worms use marine mammals or piscivorous birds as definitive hosts, with aquatic invertebrates and fish as intermediate hosts (Chai et al., 2005). The intermediate phase of these round worms encyst within the musculature of their hosts and are pervasive in their choice of host, having been found in anchovies in Italy, salmon in Norway and Japan, and in herring, cod, tuna and sardine species globally, just to name a few.

Anisakiasis is the infection of these encysted round worm larvae specifically from species in the *Anisakis* and *Pseudoterranova* genus. These larvae are ingested and attempt, unsuccessfully, to develop within the gastrointestinal tract of humans. Typically, the worm elicits an immune response in human immune systems that causes severe pain, nausea and vomiting. *Anisakis* species are also known to cause allergic reactions in humans due to a biochemical release as a defensive strategy against the host immune system. Within fish processing factories, asthma, conjunctivitis and contact dermatitis have been observed in workers who work in direct contact with fish that are infected with these parasites (Nieuwenhuizen et al., 2006).

Diphylllobothriasis is an infection caused by species from the *Diphylllobothrium* genus. This parasite's life cycle is highly complex, with two intermediate hosts and fish-eating mammals or birds as its definitive host. Infection is usually obtained through the eating of the developmental stages of the parasite present in anadromous fish musculature, particularly salmonid species. Most infections are asymptomatic with rare symptoms including abdominal discomfort, diarrhea, vomiting and weight loss (Olsen, 1986; Chai et al., 2005).

Fisheries and Aquaculture

Parasites can significantly contribute to financial losses for the fisheries industry (Lafferty et al., 2015). Regardless of whether they pose an actual health risk, the appearance of parasites in fish and the presence in the musculature can lower the value of fish products and can prevent them from being sold on local and international markets. It is difficult to measure the impacts of parasites on wild caught fish, as the prevalence on wild caught fish is comparatively lower than fish sold from aquaculture (Costello, 1993; Shinn et al., 2015).

Aquaculture is predicted to contribute 65% of our fish needs by 2030 (FAO, 2016). Therefore, there is an expected increase in aquaculture production to meet this demand. As parasitic infestations threaten the sustainability of the industry, environment and food security for a growing global population, the development and implementation of measures to lessen parasitic diseases and improve the farmed organisms' health have important social, economic, environmental and political implications.

Parasites with direct host to host transmission tend to thrive when their hosts are at a high density, as in intensive fish farming. The most significant parasites in salmon farming are species of copepods called sea lice (Family Caligidae). In the north Atlantic and Pacific oceans, two louse species, *Lepeophtheirus salmonis* (which is specific to salmon) and *Caligus elongatus* which is not host specific, cause significant costs to salmon farms (Costello, 1993, 2006). For both these species, lice from wild fish colonize fish farms. Once established within these farms, they become parasitic reservoirs and act as year round sources of lice that cross-infest surrounding wild fish populations, causing significant mortality in Ireland, Scotland, Norway, Canada, and Chile (Costello, 2009a).

Various methods are employed to control lice infestations. These include biological control methods (e.g., vaccines against bacteria, cleaner-fish to remove salmon lice), chemical treatments (e.g., pesticides and disinfectants) and changes in nutrition to strengthen fish immune systems (Costello et al., 2001). The most effective methods are to prevent or delay parasite infestation by not having overlapping generations of fish on the same farm and having 'fallow' periods when no host fish are on the farm site (Costello 2006). Apart from the monetary costs of incorporating these treatments, the environmental costs can also be substantial, particularly the aforementioned impact on wild fish populations.

Shinn et al. (2015) provided a review of global marine and brackish water aquaculture industries and used examples from these industries to try and predict the economic losses associated with the infection of key parasitic disease events within the industry. As an example, *Salmo salar* (Atlantic salmon) constitutes one of the most established aquaculture industries to date with over 40 years of experience. Globally, the farmed salmon industry is worth over \$15.4 billion USD (FAO, 2016). In 2006, caligid copepod ectoparasites, particularly *Lepeophtheirus salmonis*, added 6% to the global production cost (Costello, 2009b). This is a major constraint to a global industry and has consequences all the way down the supply chain to the consumer.

Parasites represent a key constraint to production, sustainability and economic viability in aquaculture (Timi and Mackenzie, 2015). Although some infections are predictable due to experience within the aquaculture industry, there are substantial costs associated with the control and management of outbreaks that have consequences throughout the supply chain (Costello, 2006, 2009b).

Parasites in Applied Research

Although parasites have a bad reputation and are considered “reprehensible citizens,” they have been shown to be important in contributing to understanding how ecosystems function (Poulin, 2007). This section will discuss the usefulness of marine parasites in applied research, from providing unique perspectives on how pollution is impacting biota to providing information on the structure of their host populations. Finally, we address the potential impact that climate change may have on parasitic species and the potential consequences on their hosts.

Biological Indicators

Fish parasites have been used as biological indicators to provide information on aspects of hosts’ feeding ecology and behaviour, including in remote areas such as Antarctica (Palm et al., 2007). As most fish parasites with complex life cycles are transmitted through the food chain, they can provide information on food web interactions that may not be seen through traditional stomach content analyses (Lafferty et al., 2008). For example, researchers creating a food web in the Baltic Sea found that using known parasitic infections through the food web provided more information on the food web structure than looking at the observed diet alone (Valtonen et al., 2010). A secondary benefit to this research is to discover the intermediate hosts of the parasite species and, as a result, clarify parasitic life cycles (Marcogliese, 2002). This research has been extended to provide information to fisheries managers on fish population structure during stock assessments (Timi and Mackenzie, 2015).

Fisheries stock assessments are conducted to assess the biological status of fisheries and inform managers as to the state of that fishery (Catalano et al., 2014). For example, Reed et al. (2012) identified that a “tetracotyle” type metacercaria (digenetic trematode) infecting the eyes of sardines was a useful biological tag because of its site specificity, ease of detection and probable long life span in its sardine host. By collecting, analyzing and modeling over 5,000 sardines-worth of parasite prevalence, infection intensity and abundance, Weston et al. (2015) found that there were two separate stocks of sardine. This information has allowed South African fisheries managers to better manage this fishery.

As parasites can be specific to a host family, genus and/or species, they can also be used in host identification. For example, diphyllidean cestodes assist in confirming identification of species of rays around Britain (Williams, 1964). Other parasites have been used in clarifying phylogeny, particularly in determining the host’s and parasites taxonomic positions. Olson et al. (2010) found that trypanorhynch cestodes formed two primary lineages and were monophyletic. This split provided independent support for rejecting the notion that rays are derived from sharks and supported the most recent molecular phylogenetics of the Neoselachii in which modern sharks are considered a sister group of skates, rays and saw fish.

Environmental Indicators

Parasites have been used as indicators of environmental change in two distinct ways, as effect indicators and as accumulation indicators (MacKenzie, 1999; Williams and MacKenzie, 2003; Sures et al., 2017). Effect indicators are parasites that are either positively or negatively impacted by changing environmental variables, and it is this change in population structure that is measured. Blonar et al. (2009) provides a meta-analysis of the effects of various sources of pollution (e.g., pesticides, metals, eutrophication, and sewage) on parasite populations, and they identify which parasite taxa and pollution sources effect these populations. They conclude that communities of digenean (trematode) and monogenean helminths are negatively impacted by changes in their environment, particularly heavy metals, eutrophication and sewage. The researchers conclude that by monitoring population-level changes in these taxa, parasites can provide information on the relative health of polluted areas.

Accumulation indicators are species that accumulate substances, such as toxins, from their surroundings and concentrate these substances within their tissues and organs. Historically, free living organisms, predominantly mussel species (Zuykov et al., 2013), have been used in pollution studies. Helminth parasites, particularly Acanthocephala, Cestoda and Nematoda, are susceptible to heavy metal accumulation due to their site of infection within the stomachs of their hosts. Parasites that have been identified as potential indicators have been measured with heavy metal concentrations orders of magnitude higher than the surrounding host tissues (Morris et al., 2016; Nachev and Sures, 2016).

Compared to mussels and other free-living sentinel species, parasites are small, cryptic and difficult to retrieve from their environment. This makes them unattractive to include in accumulation studies. However, as parasites occur throughout marine food webs and reside within hosts for extended periods of time, the monitoring of metals in their tissues can deliver information about the spatial and trophic distribution of pollutants, information traditional benthic sentinels cannot provide (Sures et al., 2017).

Parasites’ Potential Response to Climate Change

Local studies on warming events indicate that global climate warming may impact parasite biology and ecology. Changes that have been recorded in the protozoan parasite *Perkinsus marinus* include an increased pathogenicity in oysters along the east coast of North America during uncharacteristic winter warming events (Harvell et al., 2002). Similarly, warmer winters have led to increased invasions by copepod parasite species on aquaculture farms (Callaway et al., 2012). In some cases, it is the duration of low winter

temperatures, rather than the minimum temperature, that is most important for maturation, mortality, and re-infection within some parasite populations (Marcogliese, 2001). An increase in average winter sea surface temperatures will allow parasites to survive through the winter and consequently allow for increased survival and earlier maturation in the spring.

As temperature increases and biochemical reactions speed up, this increased metabolism is limited by the amount of fuel an organism has access to (Lafferty, 2009). As parasitic organisms depend on their host for food, an increase in temperature has the ability to increase the parasites pathogenicity on the host. Therefore, not only does the host have to deal with their own increased thermal stress, but also an increase in parasite pathogenicity (Marcogliese, 2001). For example, with increases in temperature, dissolved oxygen levels in the water decrease, which increases stress to the fish. Concurrently, a rise in temperature may shorten generation time and increase growth rates of gill parasites (such as monogeneans). The combination of decreased oxygen and increased parasite burden can cause respiratory problems for fish, often resulting in mortality (Marcogliese, 2001).

More importantly, though, increasing temperatures have been shown to alter the seasonality and biogeographical range of many species (Hillebrand et al., 2018). These range shifts will undoubtedly affect their associated parasites. This could potentially result in parasitic organisms discovering new hosts and may cause unprecedented pathogenic outbreaks in naïve host populations. In addition, these range shifts could cause local extinctions of parasitic species (in the case of host specialist species) and consequent indirect effects to ecosystems (Strona, 2015).

Conclusions

This article demonstrates the biology, ecology and societal importance of marine parasites. As evidenced by the examples of parasites in food web studies, these organisms have contributed significantly to our understanding of the direct and indirect impacts of parasites in controlling host populations (Marcogliese, 2004; Lafferty et al., 2008). In their use as biological and environmental indicators, parasites have not only allowed researchers to understand the trophic structure of ecosystems but have shown their ability to be used as sentinels within environments to provide information on host population structure and the impact that pollution may be having on an ecosystem (MacKenzie and Abaunza, 1998; Palm, 2011; Nachev and Sures, 2016).

As technology advances, with respect to genetic analysis and general taxonomic methodology, researchers are still discovering hundreds of species annually due to efforts in parasitic description being at their highest rate ever (Costello et al., 2013b; Poulin and Presswell, 2016). While perhaps most parasites have been named (Costello 2016), this is only the first step in understanding their biology and ecology (Rohde, 2002; Chaudhary et al., 2016; Poulin and Presswell, 2016; Jorge and Poulin, 2018).

Poulin et al. (2016) provide their perspective on the current state of marine parasitology and its collaboration with marine ecology and identify challenges to inter-field collaboration. These challenges include: a need for greater awareness of parasitology in general ecological journals; keeping parasitology relevant with current trends in general ecological theory; maintaining or improving current discovery rates of parasitic species and their life cycles; increasing our footprint of research into more geographic areas (e.g., open and deep oceans); and finally developing models to understand transmission dynamics of parasites. What their article highlights is that parasitology as a discipline can and should depend on more established disciplines such as marine ecology to guide its future endeavors.

Climate change is likely to impact parasite communities directly through changes in environmental conditions and indirectly through changes in host species. Therefore, the current challenge for parasitologists and conservationists is to understand the ecological roles played by parasites so as to predict how and which ecosystem functions may be altered as climate changes.

Abstract

The Isopoda are a large and morphologically diverse group of crustaceans. Roughly 6250 of the 10,300 described species are marine or estuarine. The taxonomic description of isopods started in 1840 and shows two strong phases of discovery and although the discovery rate has slowed down since the 1990s, the Isopoda are a promising group for more new species discoveries in the future. The order has a worldwide distribution occurring in terrestrial, freshwater, and marine habitats. Marine isopods can be found from pole to pole in each of the worlds' oceans. The majority of the known species occurs in shallow-water habitats, but isopods are also widely distributed in the deep sea with the Asellota as the dominant group at these depths. Some isopod families have evolved a parasitic life-style, displaying different life histories and often a highly modified appearance. Those parasites do not only infest wild host populations, but also frequently cause problems in fish farming and commercial fisheries. As marine woodborers some species, too, cause considerable damage to man-made marine infrastructure.

Systematics and Taxonomy

The order Isopoda is one of the largest orders of crustaceans with about 10,300 described species, of which roughly 6250 are marine or estuarine (Poore and Bruce, 2012). Just like so many other animals and plants the first isopods were named by Linnaeus (1707–78). However, for marine isopods the history of discovery started in 1840 when Milne Edwards' paper on Crustacea was published (Poore and Bruce, 2012). In the beginning important contributions to the taxonomy of the Isopoda were made particularly by experts from Europe and North America. History shows clearly two strong phases in the discovery of new marine isopod species. The first phase stretched from the 1880s to the 1930s and the second was during 1980s–2000 (Poore and Bruce, 2012). In the modern era new sampling methods made the sampling of very small size classes and so far unsampled habitats possible, which led to a series of new discoveries. Since the 1990s the rate of species discovery has slowed down. During that decade about 20% of all known species and 10% of the known genera were described (Poore and Bruce, 2012). Although a lot of isopod species are already scientifically described, there still remain many to be discovered in the future.

Scientists agree on the Isopoda being a monophyletic group. Such a consensus does not exist when it comes to the relationship of the group to other peracarid orders. Peracarida is the superorder which comprises the Isopoda and 11 other orders of crustaceans. Several cladistic analyses have been made; some of them stating the isopods are a sister taxon to Tanaidacea, others see them more closely related to Amphipoda (Poore and Bruce, 2012). Even on genus and species level the taxonomy is constantly changing. Over the years many species names have been revealed to be synonymies, as have some genera. For example Smit et al. (2014) mentioned in their review on the global diversity of the fish-parasitic family Cymothoidae that 16 of its genera and 83 species are in synonymy. Seven additional species therein were regarded as *Nomina dubia*, where it was doubted that they were valid species names.

Morphology

As crustaceans isopods have a segmented, chitinous exoskeleton with jointed appendages. The overlapping, articulated tergites (dorsal plates of each body segment) provide protection as well as flexibility. Isopoda have a dorsoventrally flattened body, which can be divided into three regions: the head (cephalon), thorax (pereon), and abdomen (pleon). Each body segment bears a pair of appendages. The segments of the head are fused and the respective appendages from anterior to posterior are the first pair of antennae (or antennules), second antennae, mandibles, maxillules, and maxillae (Poore and Bruce, 2012). The first thoracic segment (and sometimes the second) is fused to the head and its appendages are modified into maxillipeds which help processing food (Barnes, 1980). The head also bears a pair of well-developed compound eyes, which are always sessile in isopods. The pereon

consists of seven free segments, each bearing a pair of pereopods, which are uniramous (unbranched) and usually adapted as walking legs. The pleon has six segments, of which the last one is fused with the telson forming a pleotelson (Poore and Bruce, 2012). The abdominal appendages are called pleopods and are biramous and lamellar. The last segment of the abdomen bears a pair of biramous uropods, which can be either fan-shaped or styliform (slender and pointed) (Barnes, 1980). In contrast to most other crustaceans the Isopoda are lacking a carapace, which usually forms a branchial chamber to protect the gills (Barnes, 1980). Probably as a response to the reduction of the carapace the respiratory structures have shifted from the thorax to the abdomen. In isopods the pleopods function as gills (Brusca et al., 2016). Female isopods have a special ventral brood pouch, the marsupium, formed by oostegites (cuticular lobes extending from pereopodal coxae). The juveniles hatch inside the marsupium and are actively released by the female as manca larvae. The manca stage lacks the last pair of pereopods, but otherwise resembles an adult isopod (Poore and Bruce, 2012). The missing pair of appendages appears when the juveniles molt into adults. A synapomorphy, in other words a characteristic all groups of isopods share and which is derived from their last common ancestor, of the Isopoda is the biphasic molting. When the old cuticle is shed to enable an increase in body size, isopods first shed the posterior part of the body and later they molt the anterior part (Brusca et al., 2016). The period between the successive molts, the so called interecdysis, can take from several hours up to a few days (Kaïm-Malka, 1997).

The size range spans from 0.5 mm to as big as 500 mm in the giant isopod *Bathynomus giganteus* A. Milne-Edwards, 1879. The majority range between 3 and 20 mm (Poore and Bruce, 2012). Isopods are mostly cryptically colored or patterned. Some may show a certain degree of ornamentation or spines across their body surface. They usually have separate sexes, although there are some hermaphroditic species. While in most isopods there is none to very little sexual dimorphism, in parasitic species it may be marked (see Fig. 1I and J for sexual dimorphism in Gnathiidae) up to dwarf males and large and highly modified females. Isopods are a morphologically very diverse group (see Fig. 1). Sometimes some body segments are fused and some appendages lacking or

Fig. 1 Diverse forms of isopods. (A) Arcturidae: *Neastacilla tuberculata* AIM MA76468, with long antennae and an elongated body; (B) Paranthuridae: *Paranthura punctata* AIM MA80474; (C) Bopyridae AIM MA31344; (D) Cirolanidae: *Cirolana* sp. AIM MA124551, ventral view, displaying the typical elliptical body shape of an isopod; (E) Idoteidae: *Idotea metallica* AIM MA4568; (F) Serolidae: *Serolis polita* AIM MA31576, trilobite-like appearance; (G) Scyphacidae: *Scyphax ornatus* AIM MA100630; (H) Plakarthriidae: *Plakarthrium typicum* AIM MA75430, ventral view, extensions of coxae and peduncular articles of antennae forming oval outline; (I) Gnathiidae: *Gnathia* sp., male with distinctive protruding mandibles, scale bar: 1 mm; (J) Gnathiidae: *Gnathia* sp., gravid female carrying about 30 eggs, scale bar: 1 mm; (K) Munnopsidae: *Munna neozelanica* AIM MA76473.

reduced. A few groups have a rather elongate and cylindrical body shape compared to the more elliptical form of the typical isopod. Parasitic isopods probably are the most modified ones. Whereas male parasites often are easily identified as isopods, female parasites are sometimes scarcely recognizable as such. Some have lost all segmentation, being only sac-like forms, not at all resembling an isopod anymore (Williams and Boyko, 2012).

Biogeography

Isopods have a worldwide distribution. They occur virtually in every habitat on earth (except in terrestrial Antarctica) and are the most successful group of terrestrial crustaceans. In fact, land-living Isopoda are the only truly terrestrial crustaceans having evolved to be completely independent of water. Marine isopods can be found in all of the world's oceans from pole to pole. Since they form such a diverse group, biogeographical studies have focused more on specific taxa or regions (e.g., Borges et al., 2014 for Limnoriidae in Europe; Brusca, 1987 for the Galapagos region) than on the global picture involving all marine isopods. Poore and Bruce (2012) did a comprehensive study on the global diversity of marine isopods, but they excluded the suborder Asellota and crustacean symbionts from it. About half of all coastal, shelf and upper bathyal species occur in temperate waters, 40% in the tropics and the remainder in polar seas (Poore and Bruce, 2012). The greatest concentration of temperate species is found in Australasia, while for the tropical regions the Central Indo-Pacific is richest in species. The fish-parasitic family Cymothoidae are most diverse in tropical waters, also with the Central Indo-Pacific holding twice as many species than other tropical regions (Smit et al., 2014). The Antarctic holds nearly four times as many species as the Arctic. Temperate species show an asymmetry in latitudinal distribution with 1.35 times as many species in the Southern Hemisphere than within the same latitudes on the Northern Hemisphere (Poore and Bruce, 2012). Parasitic isopods associated with crustacean hosts exhibit highest diversities in the North West Pacific, East Asian Sea, and Central Indian Ocean, as well as in the North East Atlantic, Antarctic, Arctic, and Mediterranean (Williams and Boyko, 2012). The distribution patterns of parasitic species are, of course, influenced by host distributions.

Habitat

Members of the Isopoda can be found in every marine habitat. Their bathymetric range stretches from the intertidal zone to the dark and cold depths of the world's oceans. Although the deepest ever recorded species (6435–7280 m) is a member of the family Antarcturidae within the suborder Valvifera (Poore and Bruce, 2012), the most diverse and species rich group inhabiting the deep-sea floors is the suborder Asellota. However, the majority of species occur in shallow-water habitats on rocky shores, muddy environments, and sandy beaches (Poore and Bruce, 2012). Isopods can be found burrowed in sand, dead wood or algal holdfasts; inhabiting worm tubes, sponges, crevices or the shells of dead molluscs; or living beneath rubble or rocks. Some species of marine isopods are also able to tolerate low salinities and are frequently found in brackish waters, like estuaries or mangroves.

Ecology and Life History

Since marine isopods are benthic animals (Barnes, 1980) without a pelagic larval phase and also not exactly long-distance swimmers, their dispersal abilities are somewhat restricted. As for many other marine invertebrates, rafting on floating objects may be considered as a common dispersal mechanism, although *Idotea metallica* Bosc, 1802 (Fig. 1E) is probably the only obligate rafter within the Isopoda (Gutow et al., 2006; Tully and Ceidigh, 1986).

Isopods display a variety of feeding methods. They are scavengers, predators, parasites, detritus feeders, and filter feeders. Their diet is herbivorous, carnivorous, or omnivorous.

When it comes to reproduction the most notable aspect, which separates isopods from other crustaceans, is that they do not produce the typical nauplius larva. Instead isopods have a larval stage called manca, which lacks the last pair of pereopods (see "Morphology"). An isopod life-cycle begins with the female laying previously fertilized eggs into a special brood pouch, the marsupium. Egg size and number of eggs are correlated with female body size (Poore and Bruce, 2012). The eggs hatch inside the marsupium and the female continues to carry the larvae. At some point the young are actively released by the female as mancas. The number of manca larvae, which are released from one female, varies with the size of the female and ranges from 10 to 1600 individuals (Poore and Bruce, 2012). The juvenile isopods undergo a series of successive molts until they reach the size of adults and sexual maturity. For an individual of *Natatolana borealis* (Lilljeborg, 1851) it may take 9–11 molts to grow from 4–5 mm to 19–20 mm in length (Kaïm-Malka, 1997).

Parasites

Only a few isopod families are parasitic, but those may be very species-rich. For example the family Bopyridae contains 605 species in 167 genera in 10 subfamilies (Williams and Boyko, 2012; WoRMS, 2018). Bopyrids (Fig. 1C) parasitize other crustaceans like hermit crabs or shrimps, whereas other isopods are fish-parasitic (Smit et al., 2014). Not only teleost fishes are suitable hosts.

Elasmobranchs are also parasitized by isopods (Smit and Basson, 2002). Even other isopods end up being hosts for their parasitic relatives. Some species of Cabiropidae can be found in the brood chambers of bopyrids, which is termed hyperparasitism (Williams and Boyko, 2012). Within the Isopoda both ecto- and endoparasitic species can be found. Usually the parasites have a specific site of attachment, either somewhere on the host's body surface or in the branchial chamber or the mouth of the host. In cymothoids, for instance, the attachment site is species specific or sometimes even specific for a certain genus (Smit et al., 2014). Cymothoidae infest only one host during their life cycle. The larvae are released as a free-swimming manca stage and are immediately infective to suitable hosts (Adlard and Lester, 1995), even though they can remain free-swimming for several days while feeding on their yolk stores (Smit et al., 2014). The larvae seek a suitable host and attach to it, then they undergo successive molts into the adult stage. The juvenile first becomes a male in case there's already a female present. If no female is present, the male will transform into a larger female, which is then referred to as an adult (Smit et al., 2014). Other parasitic isopods associated with crustacean hosts infest two hosts during their life cycle, the intermediate host being a pelagic copepod (Williams and Boyko, 2012). After the larva has molted into the infective stage for the definite host, it detaches from the copepod and seeks a suitable crustacean host like some kind of crab or shrimp. It transforms into a juvenile and moves to the final attachment site. Sex determination in parasitic isopods is not fully known, but in many cases the first isopod that settles on a host becomes a female and subsequent individuals develop into males (Williams and Boyko, 2012). Females feed on the hemolymph or ovarian fluids of the host, whereas males are not known to do so. In contrast to other obligate parasites members of the family Gnathiidae are only parasitic during their larval stages. The adults (see Fig. 11 and J) are free-living forms, do not feed at all and form harems within the substrate or sponges (for a review on gnathiid isopods see Smit and Davies, 2004).

One parasitic isopod that managed to get at least some attention from a nonscientific audience is the tongue-replacing isopod, *Cymothoa exigua* Antarcturidae and Meinert, 1884. Brusca and Gilligan (1983) report on the not only structural but also functional replacement of the hosts' tongue. *C. exigua* infests fish hosts. Females attach in the mouth, while males attach to the gills. The blood-feeding of the female parasite leads to a decrease in blood circulation in the tongue and results in the degeneration of the organ. At that stage the isopod is found attached to the remaining tongue stub replacing the degenerated host structure. Parasitized fish seem to be in a good condition (Brusca and Gilligan, 1983) and there is evidence that the host uses the isopod as a kind of artificial tongue during food processing.

It is not uncommon that isopod parasites act as parasitic castrators. Parasitic castration is defined as an intensity-independent prevention or blockade of host reproduction by taking up the host's whole reproductive energy (Lafferty and Kuris, 2009). In their review on parasitic castrators Lafferty and Kuris (2009) note that the parasites may range in body mass from 3% up to 50% of their host's body mass and that some parasites, like bopyrid isopods, castrate their hosts without specifically targeting reproductive tissues. Fogelman et al. (2009) report on the effects of the cymothoid isopod *Anilocra apogonae* Bruce, 1987 on a cardinalfish. In accordance with the principle of parasitic castration the intensity of parasite infestation was always limited to one adult per parasitized fish. Parasites were also relatively large, weighing about 3.8% of the host's weight (Fogelman et al., 2009). Infested fish had significantly smaller gonads than unparasitized individuals. Moreover, parasitized female cardinal fish produced significantly fewer ova, of which only a few were mature. Male fish seemed to lose their ability of mouthbrooding. They also had a negative impact on the growth rate of their vertebrate hosts.

Economic and Environmental Impact

During the glory days of seafarers it wasn't huge and terrifying sea monsters which posed the biggest threat to ships built out of wood. Marine woodborers (shipworms, pill bugs, and gribbles) caused extensive damage to wooden vessels and marine infrastructure throughout the centuries. An estimation of the global damage caused by woodborers in the early 2000s was stated at US\$1 billion per year (Raya et al., 2015). However, the biggest amount of the damage is caused by shipworms, which are bivalves of the family Teredinidae. Woodboring crustaceans are species belonging to the isopod families Sphaeromatidae and Limnoriidae, commonly referred to as pill bugs and gribbles, respectively. Unlike members of the Limnoriidae sphaeromatids do not ingest wood as a food source, but rather simply excavate burrows utilized for shelter (Si et al., 2002). The greatest diversity of marine woodborers is found in tropical coastal water bodies (Raya et al., 2015). This pattern is consistent with the natural distribution of mangrove forests, which represent the natural habitat of marine wood-boring organisms. Along the southwestern coast of Florida the wood-boring isopod *Sphaeroma terebrans* Bate, 1866 caused a gradual shrinking of the mangrove forest area during the mid-20th century (Rehm and Humm, 1973). Woodborers also caused problems in communication technology by attacking submarine cables. In 1916, for example, the isopod *Limnoria lignorum* (Rathke, 1799) was identified as the cause of a break in the Cook Strait Cable, one of six telegraph cables connecting New Zealand's North and South Island (Raya et al., 2015).

Parasitic isopods can cause great losses in commercial fisheries and fish farming. Stepien and Brusca (1985), for instance reported nocturnal attacks of cirrolanid isopods on caged giant kelpfish *Heterostichus rostratus* at the coast of California. It was observed that the fish showed great distress once specimens of *Cirrolana diminuta* Menzies, 1962 were present. The isopods inflicted major damage to the gill filaments, as well as to the gonads and livers of fish, causing high mortality. In India cultured catfish *Mystus gulio* suffered serious lesions and anorexia from infections with *Cymothoa indica* Schioedte and Meinert, 1884 leading to mass mortality (Rajkumar et al., 2005). Within 10 days 100% of the fish stock died. Even when infections are not as severe and do not cause parasitized fishes to die, the resulting smaller sizes, lower weights, lesions, and/or deformations make the product unattractive to customers (Čolak et al., 2018). Often the cultured hosts are not the same host species which are known to be infected by the

respective parasites in the wild (Rajkumar et al., 2005; Smit et al., 2014). Methods against isopod infections in aquaculture (other than manual removal) include chemical treatments (see Costello, 1993), of which deltamethrin and diflubenzuron have been shown to decrease parasite prevalence with low toxicity for the fish in Mediterranean fish cultures (Athanasopoulou et al., 2009). Not only teleost fishes but also commercially important crustaceans like shrimp, king crabs, and brachyuran crabs are parasitized by isopods, negatively affecting the salability of infected hosts (Williams and Boyko, 2012). On the other hand isopods can be the good guys, when they—in their role as scavengers—remove waste feed from tuna farms in South Australia, diminishing the ecological impact of aquaculture on the ecosystem (Svane and Barnett, 2008).

Although humans do not rank among typical hosts for parasitic isopods, there are records of attacks on humans. Garzón-Ferreira (1990) reports being bitten numerous times by the usually fish-parasitic isopod *Rocinela signata* Schioedte and Meinert, 1879 during snorkeling at the coast of Colombia. The isopod began to feed immediately after attachment and sometimes it attached itself so firmly to the skin that it was necessary to kill it in order to remove it. Of course this case is rather an exception than the general rule.

In July 2017 a human body was retrieved from Australian waters, which showed extensive postmortem predation of the skin and subcutaneous tissues (Tiemensma et al., 2017). From the affected sites five isopod specimens were removed and identified as two different species of the family Cirolanidae, well-known marine scavengers.

Summing it up one can note that even though isopods are only very small creatures, they can cause severe problems. Also, since they are distributed worldwide, these problems are not locally restricted. So far a lot of effort has been put into isopod taxonomy, but still many more species remain to be discovered and named. The life histories of many groups and species are often poorly studied and very little is known about the ecology of deep-sea isopods and their role in this remote environment. These and other research gaps remain to be filled.

Abstract

Mesophotic coral ecosystems have been studied for almost as long as researchers have studied shallow coral reefs. This may be surprising, given that the term mesophotic was coined as recently as 2008. At their shallowest, most agree, mesophotic reefs are found between depths of 30 and 40 m. This reef zone then extends to the limit of photosynthetic activity in hard corals, a maximum depth of about 165 m. The mesophotic zone has been further divided into an upper and lower mesophotic zone either side of a global 60 m depth boundary. The lower mesophotic harbors a biota distinct from shallow reefs, while the upper mesophotic is a transitional zone between the two. The mesophotic environment can be characterized as low in light, temperature, and wave action in comparison to shallow reefs.

Background

Marine biology as a field has always faced challenges of access. Utilizing newly developed SCUBA and submersible technologies in the 20th century opened the marine environment to detailed study by scientists. SCUBA allowed taxonomists to document new taxa otherwise missed in complex 3D habitats and to adopt experimental approaches to subtidal ecology (Eschmeyer et al., 2010). Despite this, SCUBA studies have been largely limited to depths shallower than 30 m so as to remain within recreational dive regulations. Meanwhile advances in video techniques with submersibles and remotely-operated vehicles (ROVs) allowed the study of deep-water ecosystems hundreds and thousands of meters beneath the surface (Costello et al., 2005; Roberts et al., 2008). However, submersibles, are expensive to hire and operate, historically lacked dexterity, and may miss small taxa. The large ROVs necessary for taking biological samples face operational difficulties in shallow waters (e.g. overheating of cables). Typically, submersible and ROV studies have focussed on ecosystems below the ranges of zooxanthellate corals (for some exceptions see Fricke and Meischner, 1985; Fricke and Knauer, 1986). The different limitations of these methods permitted an understudied depth zone to form. A 2008 review (Menza et al.) reported 90% of all publications mentioning coral failed to report data deeper than 30 m. On the other hand, research has shown that photosynthetic hard corals regularly occur far deeper than 30 m. The current depth record stands at 165 m at Johnston Atoll (Maragos and Jokiel, 1986). This is not a globally unusual case, with further depth records set for the Bahamas, Red Sea, and Great Barrier Reef past depths of 100 m (Englebert et al., 2014; Reed, 1985; Schlichter et al., 1986), as reviewed by Kahng et al. (2010).

In 2008 a workshop was hosted by the National Oceanic and Atmospheric Administration (NOAA, USA) to bring together researchers interested in studying the hard to access “middlingly deep” coral reefs. These were the reefs found below recreational dive limits, but not the “deep” cold water coral reefs found usually beneath the photic zone formed by azooxanthellate or facultatively zooxanthellate corals (Roberts et al., 2008). They coined the term Mesophotic Coral Ecosystem (MCE), to help coordinate research and define shared research interests (Puglise et al., 2009). MCEs were meant to be recognized by their distinct ecology,

as the low light areas of reefs containing photosynthetic hard corals (Baker et al., 2016a). In practice, the term mesophotic has been applied to studies deeper than the 30 m limit of recreational diving (Laverick et al., 2018).

As hard corals typically rely on photosynthesis to satisfy their calorific demand, and light energy decreases exponentially with increasing depth (Fricke and Knauer, 1986), we would expect MCEs to be subject to a differing ecology to shallow reefs. Research on MCEs, plugging the knowledge gap reported by Menza et al. (2008), has become increasingly common as a result of advances in diving technology, autonomous exploration (Pyle, 1998), and the realization MCEs significantly increase global reef area (Harris et al., 2012).

Despite increasing research effort, how to recognize an MCE is still open for discussion. An absolute upper depth limit of 30 m fails to capture the variability of environmental conditions responsible for changing rates of reef transition between sites (Laverick et al., 2017). A number of site descriptions discuss changing richness with depth and identify clusters of deep and shallow species (Bridge et al., 2012; Muir et al., 2015), yet very few attempt to define reef structure in terms of indicator taxa (Bejarano et al., 2014). Following the second international MCE workshop in 2014 the need to address such issues was acknowledged (Loya et al., 2016).

As well as background on how the field of mesophotic research came to be, this article aims to give the reader an introduction to the evolving use of key terminology and existing research foci. The field already has a number of excellent reviews, technical reports, and recently a book (Loya et al., 2019). These resources are listed at the end of this article for those interested in reading more thoroughly about MCEs.

Key Terms

Mesophotic Coral Ecosystems (MCEs)

[MCEs] are characterized by the presence of light-dependent corals and associated communities typically found at depths ranging from 30–40 m and extending to over 150 m in tropical and subtropical regions. The dominant communities providing structural habitat in the mesophotic zone can be comprised of coral, sponge, and algal species.

(Puglise et al., 2009, pV)

MCEs are defined by their ecology, not their absolute depth range.

(Baker et al., 2016a, p12)

Initially, the term ‘Mesophotic Coral Ecosystem’ was coined to bring together researchers with an interest in studying a difficult to access system. Though the original definition published states a range that MCEs can begin from (30–40 m), there is little to no guidance on how to apply this range. Consequently, most researchers use 30 m as a static depth limit (Laverick et al., 2018). This is despite later clarification that MCEs are defined by their ecology and not a depth limit (Baker et al., 2016a,b). How to recognize an MCE in the absence of depth information, is therefore an active area of research (Laverick et al., 2017; Loya et al., 2016; Tamir et al., 2019). Additionally, it is worth noting that Scleractinia may comprise only a minor component of benthic diversity by area. In spite of whether a reef is dominated by sponge, algae, or other groups instead, the term MCE is currently used to refer to these reefs as well (Puglise et al., 2009).

Upper and Lower Mesophotic

...The upper mesophotic is home to many shallow-water marine organisms and represents a transition zone between shallow-water and lower mesophotic communities. The lower mesophotic represents a distinct community with some species exhibiting special physiological adaptations.

(Kahng et al., 2014, p72)

Many MCEs within the Caribbean Sea exhibit a clear demarcation between the upper mesophotic community (30–60 m), with biodiversity that overlaps with the shallow coral reefs, and the ecologically distinct lower mesophotic community (60–100 m).

(Lesser et al., 2018, p62)

Shortly after the term mesophotic entered the literature, a distinction was made between the upper and lower mesophotic (Kahng et al., 2014). The upper mesophotic represented an area of overlap, containing some shallow species, while the lower mesophotic contained its own taxa. Kahng et al. (2010) initially reviewed a number of ecological papers reporting a split in community structure in the mesophotic zone. As would be expected, the depth these boundaries occurred at was variable by region and taxon. However, researchers have settled on a ‘60 m rule’ to currently divide MCEs (Lesser et al., 2018). The 60 m rule has been validated with a global meta-analysis, showing the upper- lower mesophotic boundary can be detected as the loss of shallow taxa (Lesser et al., n.d.).

Temperate Mesophotic Ecosystem

As a notable number of researchers understood the word mesophotic to mean a depth zone below 30 m (Fig. 1A), it did not take long before it was used to refer to ecosystems other than tropical and sub-tropical MCEs (Bo et al., 2011). In order to reflect the growing use of the term mesophotic in temperate regions, the term temperate mesophotic ecosystem (TME) was used in a workshop at the European Coral Reef Symposium in 2017. TMEs have now worked their way into the categorization process of the research depository [Mesophotic.org](https://mesophotic.org) (Bongaerts et al., n.d.), and the recent mesophotic coral ecosystems book (Loya et al., 2019). The current use of the term TME follows Fig. 1A for MCEs, but at temperate latitudes.

Mesophotic

Though MCEs were defined in the 2009 research strategy, use of the term mesophotic (literally meaning middle light) as an adjective has been more fluid. Initially, researchers used the word mesophotic as a short-hand for reefs deeper than 30 m (Fig. 2A; Laverick et al., 2018). It was this behavior which caused TMEs to enter our vocabulary, as discussed above. Introducing the upper and lower mesophotic (Fig. 2B) advanced the term towards ecological features, as agreed during collaborative exercises (Baker et al., 2016a; Puglise et al., 2009). However, why is it the upper mesophotic, instead of the lower shallows? The upper mesophotic is agreed as the area of community overlap between shallow and mesophotic taxa. As such, mesophotic has also been used to describe communities distinct from shallow reefs (Semmler et al., 2016; Laverick et al., 2017; Baldwin et al., 2018; Rocha et al., 2018; Fig. 2c). Shallow and mesophotic communities may overlap at the limits of their depth ranges, but crucially, these depth limits are site-specific. Identifying groups of taxa as either shallow or mesophotic is a more flexible approach, which permits the investigation of community level processes and can help avoid comparing apples and oranges. We raise these points now, as the use of language can cause confusion when discussing reef recovery processes later.

Biodiversity

Our knowledge of the biodiversity on MCEs has improved greatly. The number of publications considering MCEs has trebled (Laverick et al., 2018) since Menza et al. (2008) quantified the knowledge gap. Yet, there are notable biases any reader should be aware of before the discussion of broad patterns. Almost 80% of publications come from the western Atlantic or the Hawaiian archipelago, as opposed to the Red Sea, Indian Ocean, the Coral Triangle, and the Great Barrier Reef (Fig. 3; Turner et al., 2017; Laverick et al., 2018). Our knowledge base is also heavily skewed taxonomically. Both systematic reviews by Turner et al and Laverick et al. estimate the number of species from different taxa present deeper than 30 m. Both reviews found the majority of studies considered fish or Scleractinia. Turner used 43 studies of these two groups, with an additional eight studies found for algae, and 14 studies for sponges. Laverick used 30 studies of fish and Scleractinia, and estimated richness values with four studies for different algal taxa, three studies of octocorals, and two of antipatharians. Taxa represented by a single study, such as brachyuran crabs (Hurley et al., 2015), were excluded by Laverick et al.

Fig. 1 Mesophotic Coral Ecosystems contain coral species specially adapted to low light environments, scleractinian species found on these reefs often have gracile growth forms which maximize the available surface area for light capture, but are more sensitive to changes in sedimentation or physical disturbance. Image by Jack Laverick from Utila, Honduras.

Fig. 2 A schematic representation of key mesophotic terms. *Blue lines* represent the shallow zones/species/depths. *Orange* indicates the mesophotic. The *gray box* in (b) is the area of community overlap (the upper mesophotic). *Curved lines* in (c) represent distributions of identified communities instead of depth limits. (a) Mesophotic, a difficult to access reef zone. A static depth limit is a simplification of (Puglise et al., 2009). (b) Upper Mesophotic, area of community overlap. Lower Mesophotic, distinct species below the ‘60 m rule’ (Kahng et al., 2014). (c) Shallow and mesophotic communities can be identified as assemblages of species with site-specific depth distributions. (Laverick et al., 2017) as indicated by (Baker et al., 2016a).

Fig. 3 A heatmap of study effort in the mesophotic zone, limited to the tropics and subtropics. *White dots* indicate study locations, colors indicate the density of publications, with *red areas* more often studied than *blue*. This map was generated from the [Mesophotic.org](https://mesophotic.org) databank.

In general, the geographical patterns in mesophotic scleractinian biodiversity appear to mirror those on shallow reefs. Areas with a large number of shallow coral species, such as the Great Barrier Reef and Coral Triangle, also have a large number of mesophotic taxa when thoroughly surveyed (Muir et al., 2018). Low diversity reefs in the Caribbean similarly have lower levels of diversity on mesophotic reefs. It is important to note the taxonomy of deeper species is not as refined as for shallow reefs (Luck et al., 2013), but there is currently no reason to suspect this has a geographical bias. Along depth gradients, the number of scleractinian species tends to decline monotonically, however, such patterns are affected by declining survey effort with depth (Laverick et al., 2018). This is in contrast to the abundance of corals, which may peak at intermediate depths (Tamir et al., 2019; Rooney et al., 2010). The combination of these two features means that mesophotic coral distributions can appear more patchy, with small areas of high coral cover with a low number of species (Hoeksema et al., 2016).

In contrast, the number of sponges increases with decreasing depth. A Caribbean-wide synthesis revealed that sponge densities quadruple over depth gradients of 100 m (Lesser and Slattery, 2018). This increase was not offset by decreasing colony sizes, with percent benthic cover consistently found to increase to a similar degree.

Seagrasses and algae can occur surprisingly deep, given that they are photosynthetic. Kelp beds have been found at tropical latitudes at depths of 70 m (Graham et al., 2007; Joly and De Oliveira Filho, 1967). Underwater footage has suggested crustose coral-line algae occurs as deep as 301 m in Bermuda (Stefanoudis et al., n.d.-a) and 312 off the Pitcairn islands (Friedlander et al., 2014).

Along the Great Barrier Reef seagrass beds have been found to extend to 61 m, containing up to five species. These beds became rarer with increasing depth (Coles et al., 2009). Calcareous rhodolith beds dominate MCEs of the Abrolhos Bank, Brazil (Brasileiro et al., 2015). Species richness and abundance remains fairly constant until a decline after 60 m depth. While Scleractinia, seagrass, and rhodoliths decline with depth, and sponges increase, in the Hawaiian archipelago algal taxa exhibit a peak in species richness. At around 85 m depth there are 50% more algal species than at 40 m (Pyle et al., 2016). Off the coast of Florida the peak in algal richness was between 30 and 50 m, also with an increase of 50% in comparison to shallow reefs (Hanisak and Blair, 1988). Off Bermuda, macroalgal abundance and biodiversity peaks around 60 m (Stefanoudis et al., n.d.-a; Stefanoudis et al., n.d.-b). At mesophotic depths in the Caribbean, it is not uncommon for algae to be the most abundant benthic group (Laverick et al., 2017). In the Bahamas, the limit on the abundance of the brown alga *Lobophora variegata* on MCEs appears to be grazing pressure as opposed to intrinsic physiology (Slattery and Lesser, 2014). As such, when grazing pressure is reduced, phase shifts to an algal dominated state on MCEs are possible. After the introduction of invasive lionfish, which predated grazing fish species, *L. variegata* abundance increased by 50% (Lesser and Slattery, 2011) (Fig. 4).

We know very little about octocorals and black corals (Antipatharia) on MCEs. Wagner (2015a) reported eight black coral species shallower than 150 m in the Hawaiian archipelago. These eight species had overlapping depth ranges, and as a group were most abundant around 50 m depth (Wagner, 2015b). Similarly, of seven species identified off Bermuda from 0 to 300 m depth, five were found shallower than 150 m (Wagner and Shuler, 2017). On the Flower Garden Banks, USA, black corals were observed between 48 and 115 m. Black corals appear to constitute a minor component of benthic diversity, at up to 4.5% benthic cover (Clark et al., 2014), leaving them vulnerable to overexploitation (Gress and Andradi-Brown, 2018). There are typically more octocoral species reported from mesophotic surveys than black corals. On the Great Barrier Reef peak octocoral richness at the genus level occurred at depths greater than 60 m, with rarefaction curves estimating about 37 genera (Bridge et al., 2012). In the gulf of Eilat, species richness of octocorals was higher at upper mesophotic depths, with 21 of the total 31 species recorded. Only 16% of the species were common across shallow and mesophotic depths, indicating distinct communities. This is in parallel to research finding distinct communities across depth gradients in Scleractinia (Laverick et al., 2017), and fish (Baldwin et al., 2018).

In comparison to sessile taxa, it might be expected that patterns with depth for fish may be less pronounced. The ability to move offers a route to avoid environmental fluctuations. In reality, fish communities are also structured by depth (Stefanoudis et al., n.d.-a, n.d.-b; Baldwin et al., 2018), with high rates of species discovery reported during surveys of new regions (Baker et al., 2016b). Further, a global meta-analysis revealed the shallow to mesophotic transition occurs 12 m shallower for fish than benthic taxa (Lesser et al., n.d.). Fish populations on mesophotic reefs have increased rates of geographical endemism (Kosaki et al., 2017; Pyle et al., 2016), and can be found at higher population densities (Fukunaga et al., 2016). High fish densities could be explained by comparatively high levels of exploitation on shallow reefs (Kadison et al., 2017; Lindfield et al., 2015), but not all mesophotic fish populations show higher levels of abundance (Andradi-Brown et al., 2016a). Beyond abundance, biomass may shift to different feeding guilds with increasing depth (Andradi-Brown et al., 2016a; Bejarano et al., 2011; Fukunaga et al., 2016; Stefanoudis et al., n.d.-a, n.d.-b) (Table 1).

Table 1 Example benthic taxa found on Mesophotic Coral Ecosystems around the world (Brasileiro et al., 2015; Bridge et al., 2012; Gress and Andradi-Brown, 2018; Laverick et al., 2017; Pyle et al., 2016; Shoham and Benayahu, 2016; Tamir et al., 2019; Wagner, 2015a; Wagner and Shuler, 2017)

Benthic group	Examples
Scleractinia	<i>Agaricia lamarcki</i> , <i>Agaricia undata</i> , <i>Leptoseris hawaiiensis</i> , <i>Madracis</i> spp., <i>Montastraea cavernosa</i> , <i>Montipora millepora</i> , <i>Pachyseris speciosa</i> , <i>Stylophora pistillata</i>
Octocorallia	<i>Ellisella barbadensis</i> , <i>Muricella</i> spp., <i>Rhytisma f. fulvum</i> , <i>Sinularia vrijmoethi</i> , <i>Siphonogorgia</i> spp.
Antipatharia	<i>Acanthopathes undulata</i> , <i>Antipathes atlantica</i> , <i>Antipathes caribbeana</i> , <i>Myriopathes</i> cf. <i>ulex</i> , <i>Plumapathes pennacea</i> , <i>Tanacetipathes tanacetum</i>
Algae	<i>Caulerpa</i> spp., <i>Cladophora brasiliensis</i> , <i>Dictyopteris</i> spp., <i>Dictyota</i> spp., <i>Halimeda</i> spp., <i>Lithothamnion crispatum</i> , <i>Lobophora variegata</i> , <i>Microdictyon</i> spp.

Adaptations

For the light-dependent biodiversity of the mesophotic zone, satisfying energy demands poses a significant challenge. Photosynthetically active radiation declines exponentially with depth, necessitating physiological adaptation. Here we focus on Scleractinia. To acknowledge research on other groups, we will highlight one non-coral example of adaptation to the mesophotic environment. The sponge *Plakortis angulospiculatus* has a plastic defense strategy which changes down a depth gradient (Slattery et al., 2016). In the shallows the sponge uses high levels of a chemical deterrent against spongivorous fish. With increasing depth these chemicals are present at a reduced concentration. Instead, more energy is invested in wound regeneration and protein synthesis. This trade-off exists as there is a gradient of decreasing grazing pressure with depth. Interestingly, when sponges are transplanted to different depths, they are able to alter their defenses.

Skeletal Adaptations

Perhaps the most apparent adaptation to the low-light environment is the modification of coral growth forms. As depth increases, flatter growth forms become more prevalent (Video 1 in the online version at <https://doi.org/10.1016/B978-0-12-409548-9.11904-9>). This trend is not only driven by an increase in the abundance of plating species, such as agariciid corals (Hoeksema et al., 2016), but also by plastic responses in other taxa. In the Gulf of Eilat, the branching coral *Stylophora pistillata* shifts from thick to thin branches to a plating form with depth (Einbinder et al., 2009; Nir et al., 2011). In the Coral Sea and the Great Barrier reef, corals of the genera *Isopora* and *Acropora* flatten their branches while increasing their spacing and fragility (Muir et al., 2015). In the Caribbean, mounds of *Orbicella annularis* (Dustan, 1975), *Montastraea cavernosa* (Lesser et al., 2010), and *Stephanocoenia intersepta* (pers. obs.) become flatter in low-light environments. These changes have been interpreted as increasing surface area to volume ratios of the coral holobiont for efficient light capture. A trade-off exists across depth gradients, between the need for robust growth forms in the shallows to withstand water movement, and fragile growth forms at depths for light capture.

In addition to macro-scale changes to coral skeletons, taxa common on MCEs are known to have skeletal patterns at the micron-level (Kahng et al., 2012). Kahng et al. placed fragments of *Leptoseris* spp. from Hawaiian MCEs under a scanning electron microscope, revealing repeated channels approximately 100 μ m wide. The presence of channels in the skeleton is typical of agariciid corals more generally. These structures were not present in shallow water *Porites* spp. and are suggested to help with the efficient harvesting of light by increasing internal photon scattering. This hypothesis is supported by aquaria trials showing corals which scatter light with their skeleton to a high degree are more easily bleached (expel their endosymbionts, Swain et al., 2016).

Pigmentation

Kahng et al. (2012) discuss the skeletal adaptations of *Leptoseris* spp. in the context of lower light reflectance, despite lower pigmentation concentrations than shallow *Porites*. However within a species, corals on MCEs may contain higher levels of pigment (Lesser et al., 2010). This can be achieved by increasing the density of zooxanthellae within the coral host (Bongaerts et al., 2011), and/or the chlorophyll content of each cell (Cohen and Dubinsky, 2015). These physiological changes are useful to a limit, as eventually self-shading will offset any benefit from further pigment increases (Smith et al., 2017). Nuanced changes in pigmentation are also possible, with the ratios of different forms of chlorophyll changing with depth for *S. pistillata* in the Red Sea (Nir et al., 2011). Research from the same area describes the widespread expression of fluorescent pigments by mesophotic corals (Eyal et al., 2015). Eyal et al. (2015) noted that the depths with high levels of fluorescence coincide with peaks in the abundance of mesophotic coral species. Exactly how fluorescent pigments help mesophotic corals is still a topic of discussion. Earlier in the same year Roth et al. (2015) described coral fluorescence from Hawaiian mesophotic reefs, and concluded the pigments unlikely enhance symbiont photosynthesis. This was following assessments of photosynthetic parameters of fluorescent and non-fluorescent coral colonies.

Long term aquaria trials have since shown that fluorescent proteins can improve the survival of coral colonies under mesophotic light conditions, and that this may be linked to improving the penetration of light to deeper tissues layers (Smith et al., 2017).

Discussion of the variation in *Symbiodinium* (symbiotic zooxanthellae) clades harbored by corals are closely related to those of pigmentation in corals. *Symbiodinium* clades may be stratified by depth both within and between species (Bongaerts et al., 2015). The degree of symbiont stratification observed by Bongaerts et al. (2015) correlated with their reproductive strategy. Brooding coral species tend to inherit their symbionts maternally. Broadcasting taxa instead acquire their symbionts from the environment as planulae (Kirk et al., 2013). This allows broadcasting species to be more flexible in their symbioses. Though symbiont switching within a coral colony has been recorded by shallow studies (Jones et al., 2008; Kemp et al., 2014), manipulative experiments relocating *S. pistillata* across depths have repeatedly failed to induce change in *Symbiodinium* communities (Bongaerts et al., 2011; Borell et al., 2016; Einbinder et al., 2016). Despite this, it has been suggested a more gradual acclimation period could allow for symbiont-switching to occur in this species (Cohen and Dubinsky, 2015). In the absence of evidence for symbiont switching (as opposed to zonation) on MCEs, it seems likely symbiont-zonation results from selection acting on holobionts (coral-symbiont combinations). This is rather than corals acquiring the appropriate symbiont for their location post-settlement. This will have implications for reef recoveries under shifting environments, as recruitment and growth of new colonies will be slower than changing the symbionts of established corals.

Mixotrophy

Scleractinian coral species can all be placed on a spectrum of energy acquisition between autotrophy (photosynthesis) and heterotrophy (filter-feeding). As the energy available from sunlight is lower on MCEs, it is possible that corals could increase their rates of heterotrophic feeding to compensate (Palardy et al., 2005). Heterotrophic subsidy, therefore, has been studied as a possible mechanism permitting mesophotic hard corals to thrive in low-light environments (Alamaru et al., 2009; Crandall et al., 2016; Lesser et al., 2010). Stable isotope analyses have been conducted on a variety of mesophotic species, as the relative importance of heterotrophy and photosynthesis can be inferred from isotopic signatures in tissue carbon and nitrogen (Peterson and Fry, 1987). As is to be expected, the relationship between the importance of heterotrophy and depth is species-specific. In the Caribbean *Agaricia lamarcki* derives nutrients from heterotrophy through the entire depth range, with a photosynthetic signal only apparent in the shallows (Crandall et al., 2016). Meanwhile *M. cavernosa* (Crandall et al., 2016; Lesser et al., 2010) relies increasingly on heterotrophy as depth increases.

In the Red Sea, Alamaru et al. (2009) asked similar questions of *Favia fava* and *S. pistillata*. Though the heterotrophic capacity of both species remained constant with depth, whether lipids were synthesized from heterotrophically or photosynthetically acquired carbon differed. *Stylophora pistillata* relied on photosynthesis for lipid precursors in the shallowest 15 m, below this heterotrophy becomes increasingly important. Meanwhile, *F. fava* relies on heterotrophy to synthesize lipids across its entire depth range. This is an important distinction when viewed alongside trends in the ratio of carbon to nitrogen (C/N) in coral tissue. Higher C/N values are considered a sign of good condition as key energy compounds, such as lipids and carbohydrates, become more abundant in comparison to the protein machinery of the organism. With increasing depth the C/N ratios of *F. fava* remained constant, but declined for *S. pistillata*. This suggests the higher levels of heterotrophy in *F. fava* was advantageous for life in the mesophotic zone, in comparison to *S. pistillata* which has lower energy reserves when light levels decline.

Conservation and Refuges

A sizeable portion of recent research on MCEs was inspired by a conservation angle. In 1996, when writing about coral bleaching, Peter Glynn suggested:

Possible refuge habitats that would be protected from rapid temperature rise might be found at moderate depths, in upwelling centres, on oceanic banks or island shores exposed to vigorous circulation, and at some high latitude sites.

(Glynn, 1996, p505)

From this the Deep Reef Refugia Hypothesis (DRRH) was formalized (first reviewed for the Caribbean by Bongaerts et al., 2010), positing deeper reefs may be protected from climate pressures threatening shallow reefs. If deeper reefs survived a disturbance event, they may provide recruits which contribute to shallow reef recovery. Consequently, reefs deeper than 30 m (Mesophotic sensu Fig. 2A) became an area of conservation interest. This interest only grew as threats to shallow water reefs appeared to become increasingly severe (Hughes et al., 2017). Glynn's (1996) original suggestion focussed on fluctuations in temperature and resulting coral bleaching, but the refuge potential of MCEs was recognized to apply to a wider range of impacts and stressors (Bridge et al., 2013). Physical damage associated with water movement during storms is expected to decline with depth. Similarly, deeper reefs are often also further from shore. As such MCEs may also avoid stresses associated with sedimentation, coastal development, and fishing. When discussing areas which only avoid single, short term (i.e., not on a decadal time scale) pressures such as these, one should strictly talk about deep reef refuges (singular refuge). Refugia (singular refugium), meanwhile, provide long term

buffering against multiple stressors over many decades (Kavousi and Keppel, 2017). Current studies of mesophotic reefs and the DRRH have therefore tended to consider refuges, as long time series are rare.

Directly testing whether mesophotic reefs contribute to deep reef refuges is difficult. It would require damaging multiple shallow reefs and waiting for potentially lengthy regeneration times, which could then be linked to MCEs. There are a number of assumptions, however, which must be true in order for recovery dynamics to occur on a given reef. These assumptions closely match core elements of meta-population models from other fields.

Firstly, we assume community overlap between shallow and mesophotic reefs. Only depth-generalist taxa will be able to contribute to shallow reef recovery after a shallow disturbance. We would not expect mesophotic specialist taxa to contribute to a direct replacement of shallow biodiversity, nor would we expect shallow specialist taxa to occur in the refuge in the first place. Research into community overlap deeper than 30 m on reefs has therefore been framed as a conservation question (Laverick et al., 2018; Muir et al., 2018; Rocha et al., 2018). Globally we expect 2/3 species occurring on shallow reefs to appear at depths greater than 30 m (Laverick et al., 2018). This suggests MCEs (sensu Fig. 2A) could be a significant, but not comprehensive, store of shallow reef biodiversity.

Secondly, we assume that deeper populations are not sink populations, but are reproductively active and capable of contributing to shallow recruitment. Multiple studies exist addressing the issues of fecundity with increasing depth (Eyal-Shaham et al., 2016; Feldman et al., 2017; Holstein et al., 2015, 2016; Liberman et al., 2018; Prasetya et al., 2015; Shlesinger et al., 2018), and vertical connectivity (Slattery et al., 2011; Brazeau et al., 2013; Serrano et al., 2014; Goodbody-Gringley et al., 2015; Bongaerts et al., 2017). It remains unclear how often reproduction at depth is sufficient to support shallow reef recovery; especially as this may be a balance between population size, depth dependent fecundity, and settlement probabilities (Holstein et al., 2016; Kramer et al., 2019). Never the less, the above studies document the production of propagules, and settlement, on MCEs.

Finally (though there may be more barriers), reduced mortality with depth is still simply assumed for most sites. Lower levels of damage have been observed with increasing depth after thermal anomalies (Sinniger et al., 2012; Smith et al., 2014; Muir et al., 2017; Frade et al., 2018; Laverick and Rogers, 2018). However, different stresses and disturbances have differing frequencies and intensities between sites. The Red Sea for instance is known for its high water temperatures, however, it also has a local pool of species capable of tolerating these levels (Osman et al., 2018). In Palau, shifting thermoclines can transport thermal stress from the shallows onto MCEs (Schramek et al., 2018). Taxa on mesophotic reefs may still be vulnerable because of increased sensitivities. Hard corals from more stable environments may be less tolerant of changes in ambient conditions as a result of reduced phenotypic plasticity (Oliver and Palumbi, 2011). Bleaching has been observed on MCEs (Nir et al., 2014) and in some instances the thermal susceptibility of mesophotic hard corals has been shown to be higher than shallow species (Smith et al., 2015). In addition to bleaching pressures, disease (Smith et al., 2010), and storm damage (White et al., 2013) has been observed. The fragile nature of mesophotic hard corals leaves them particularly susceptible to physical disturbance (Bongaerts et al., 2013), while the typically large plating growth forms at mesophotic depths are more vulnerable to the negative effects of sedimentation (Rogers, 1990).

It is important to note that MCEs should not be considered synonymous with deep reef refuges. Though early on it was convenient to reduce 'mesophotic' to a depth (Fig. 2A), and so the area of interest for the DRRH, this way of thinking can run into difficulties when considering the shallows and mesophotic as different communities (Fig. 2C; Laverick et al., 2016, 2017, 2018). By using a community-based definition, mesophotic reefs cannot protect shallow communities during a period of disturbance. This is relevant when interpreting the research on community overlap with depth, discussed above. Instead, deep reef refuges occur in the mismatch between the lower depth ranges of taxa, and the relationship between stressors, impacts and depth (Fig. 5-DRRH). Environmental damage is therefore a function of the vertical extent and intensity of the event, and the vertical distribution and depth-dependent susceptibilities of taxa. Though shallow taxa may extend deeper than 30 m, depth refuges may also operate over much smaller depths. In Panama, susceptibilities, depth gradients, and two coral bleaching events resulted in the extirpation of a hydrocoral only in the very shallowest portions of the reef (< 11 m; Smith et al., 2014).

Separating out mesophotic communities from the main discussions of deep reef refuges not only increases clarity, but also allows us to investigate the rather neglected issue of mesophotic conservation. MCEs face a variety of threats themselves and require protection in their own right (Andradi-Brown et al., 2016b). Though there may be realizations of deep reef refuges for mesophotic communities, not just shallow taxa, we may expect the primary threats to MCEs to behave differently to those on shallow reefs (Fig. 5-MCE Threats).

The damage to unique biodiversity on MCEs may be more severe with increasing depth in a variety of cases (Fig. 5-MCE Threats). As mentioned earlier, mesophotic taxa may be less resilient to thermal stress because of increased sensitivities (Smith et al., 2015). The invasive lionfish (*Pterois volitans*) has been implicated in phase shifts to an algal dominated state at mesophotic depths in the Caribbean (Lesser and Slattery, 2011; Slattery and Lesser, 2014). The efficacy of management options for lionfish declines with depth (Andradi-Brown et al., 2017a; Andradi-Brown et al., 2017b), resulting in high numbers on MCEs (Aguilar-Perera et al., 2017; Gress et al., 2017; Nuttall et al., 2014; Pinheiro et al., 2015). As mesophotic taxa live at the extreme end of photosynthetic performance, any events which modify the underwater light field are likely to have a greater effect than on shallow taxa. Examples of such processes could include shading induced by sediment resuspension after storms or coastal development. Similarly changes to algal blooms, either from coastal run off or climate-related drivers, could also have consequences for mesophotic taxa (Tamir et al., 2019). In this case, periods of net photosynthesis and seasonal bleaching of *Stylophora pistilata* on MCEs coincide with phases in the annual algal bloom in the gulf of Eilat/Aqaba (Nir et al., 2014). It is likely eutrophication events in this

Fig. 5 A schematic representation of threats to coral reef ecosystems, and which ones we may expect to be relevant to the conservation of shallow or mesophotic reefs. The deep reef refugia hypothesis (DRRH) considers whether shallow taxa (*blue*) can avoid shallow disturbances (*red*). As depth increases the strength of these threats is expected to decrease. The mismatch between the species depth range and the maximum impacted depth determines the size of the refuge area. Threats (*red*) more likely to affect mesophotic taxa (*orange*) are those which accumulate with increasing depth i.e. shading from suspended sediments or algal blooms. In this case the shallowest mesophotic taxa may be protected, with conservation risks being determined by how rapidly the impact strengthens with depth.

location during the 1990s (Loya, 2004) had notable effects on mesophotic communities. Only now are we able to monitor these events and call for the protection of MCEs.

Further Reading

For those interested in reading on MCEs in more detail, there are a number of excellent sources of further information. We will not provide a list of every review of the mesophotic literature. Instead, the following are the products of significant collaboration between most of the active researchers in the field at the time of publication.

- 1) The Mesophotic research strategy arising from NOAA's 2008 workshop (Puglise et al., 2009).
- 2) Released at the International Coral Reef Symposium in 2016, members of the mesophotic community worked together to publish a report explicitly considering the deep reef refugia hypothesis. The topics covered include mesophotic biodiversity, the ecosystem services it provides, and the threats it faces (Baker et al., 2016b).
- 3) Recently the state of the field was synthesized as part of Springer's coral reefs of the world book series. Chapters touch on regions, concepts, and knowledge gaps in the field; and is side by side with [Mesophotic.org](http://mesophotic.org) as one of the largest single sources of information on MCEs (Loya et al., 2019).

List of Relevant Websites

<http://mesophotic.org> is listed as one of the accomplishments of the 2008 meeting (Puglise et al., 2009). Though it has gone through a couple of different formats, its most recent incarnation is as a repository of publications and an address book of the mesophotic community (Bongaerts et al., n.d.).

Acknowledgment

We would like to thank Pim Bongaerts for providing us with the GPS points of studies in mesophotic.org.

Abstract

First used to prioritize terrestrial sites with exceptional concentrations of species, exceptional levels of endemism, under exceptional degrees of threat, the term biodiversity hotspots was extended to the marine realm in 2002. Since then there have been 18 global scale studies of marine biodiversity hotspots. The data and criteria used to identify hotspots varies within the literature. However, most research highlighted the same areas as hotspots of marine biodiversity. Species richness generally peaked in Australia, South East Asia through to Japan, South Asia, South East Africa, the Caribbean and South East United States. Centers of endemism are identified in South Africa, the East and West Coasts of Australia and isolated areas such as Hawaii, Easter Island, New Zealand, and Antarctica. Hotspots of both high species richness and high species endemism are located in the West Caribbean, South Madagascar, Chagos Islands, Maldives, Lakshadweep, Sri Lanka, South Japan, East China Sea including Taiwan, Coral Triangle, New Caledonia, Vanuatu and North East and North West Australia. Although protecting marine hotspots should be prioritized in order to protect ocean biodiversity, the distribution of species richness varies between taxa, and many centers of endemism are distinct from areas of high species richness. Therefore, protecting marine biodiversity hotspots does not represent a comprehensive strategy to represent and protect all marine life. Moreover, only four studies acknowledge the importance of protecting IUCN threatened species, yet those species are at the highest risk of extinction. Only by protecting hotspots of species richness, hotspots of endemism and threatened species can we reduce the risk of species extinction, support the recovery of marine species and protect marine biodiversity.

Introduction

Hotspots is an approach used to prioritize sites in need of conservation (Myers, 1988; Roberts et al., 2002; Briscoe et al., 2016). It was first used by Myers in 1988 to identify areas of tropical forest that featured exceptional concentrations of species with exceptional levels of endemism, under exceptional degrees of threat. Since then, the term “Hot Spots” has become synonymous with terrestrial biodiversity conservation spatial planning (Medail and Quezel, 1997; Reid, 1998; Myers et al., 2000; Ceballos and Ehrlich, 2006; Mittermeier et al., 2011). Initially extended to the marine realm and tropical reefs by Roberts et al. (2002), identifying hotspots of marine biodiversity has likewise been promoted in marine conservation (Allen, 2008; Morato et al., 2010; Lascelles et al., 2012), particularly given the emerging crisis for ocean biodiversity (Myers and Worm, 2003; Bellwood et al., 2004; Payne et al., 2016). More recently, identifying freshwater biodiversity hotspots has also utilized Myers’ approach (Oberdorff et al., 2011; Grant et al., 2012; Tedesco et al., 2012; Collen et al., 2014). Overall, the growing number of terrestrial, freshwater and marine species facing extinction far outweigh the conservation resources designated to protect them (Myers et al., 2000). Consequently, mapping and protecting biodiversity hotspots represents a cost-effective use of resources to protect planetary biota (Pimm and Raven, 2000; Roberts et al., 2002; Mittermeier et al., 2011; Marchese, 2015).

Since its inception, the term marine biodiversity hotspots has been used to describe a variety of distribution patterns. From areas with high species richness, diversity and abundance (Renema et al., 2008; Bennison and Jessopp, 2015; Descombes et al., 2015; Laptikhovsky et al., 2017), to those with high productivity, endemism, threatened species, taxonomic distinctiveness, and high threat intensity (e.g., Valavanis et al., 2004; Davidson et al., 2012; Lewison et al., 2014; Schuyler et al., 2016; Briscoe et al., 2016; Friedlander et al., 2016). However, the majority of scientific literature designates marine biodiversity hotspots as a combination of high species richness, endemism or threat, as shown by Roberts et al. (2002), Bellwood and Meyer (2009), O’Loughlin et al. (2011), Selig et al. (2014), Dulvy et al. (2014), Jenkins and Van Houtan (2016), and Ramírez et al. (2017) among others. Consequently, research has helped to define and map marine biodiversity hotspots in order to focus conservation efforts (Olson and Dinerstein, 2002; Tittensor et al., 2010; Ramírez et al., 2017).

Designating Marine Hotspots

There have been numerous small-scale studies focusing on individual taxonomic groups and species. For example, studies on biodiversity hotspots of Australian sponges in tropical and subtropical Australia (Hooper et al., 2002), cyclostome bryozoans in

Spirits Bay, New Zealand (Taylor and Gordon, 2003), and hotspots of sea cucumber biodiversity in the Antarctic (O'Loughlin et al., 2011). To date there have been 18 global scale studies of marine biodiversity hotspots (Table 1). Roberts et al. (2002) were the first to identify marine biodiversity hotspots on a global scale. They analyzed species richness and endemism of reef fish, corals, snails and lobsters, as well as threats to coral reefs from human impacts, based on coastal development, overexploitation and pollution. They designated 18 centers of endemism, from areas as small as Easter Island to areas as large as the Great Barrier Reef (Veron et al., 2011), of which 10 were deemed threatened by human impacts and subsequently defined as marine biodiversity hotspots (Roberts et al., 2002) (Table 1). Additional global scale studies have concentrated on specific groups of taxa, e.g., marine mammals (Pompa et al., 2011), sharks (Lucifora et al., 2011; Dulvy et al., 2014), and fish (Stuart-Smith et al., 2013), as well as across taxonomic groups (e.g., Tittensor et al., 2010, Selig et al., 2014, Jenkins and Van Houtan, 2016; Ramírez et al., 2017).

Marine biodiversity hotspots studies had large variations in the number of species included in each study, ranging from 121 to 12,796 (Table 1). The most detailed studies, by Molinos et al. (2016) and Selig et al. (2014), included 12,796 and 12,497 species, while studies concentrating solely on marine mammals included just 115, 123, and 121 species respectively (Kaschner et al., 2011; Pompa et al., 2011; Albouy et al., 2017). However, Worm et al. (2005) showed that species richness of tuna and billfish corresponded with other pelagic taxa across trophic levels, acting as an indicator of overall pelagic species richness (Worm et al., 2005; Tittensor et al., 2010; Trebilco et al., 2011). While 17 of the 18 studies reviewed used species richness, some based hotspots solely on species richness ($n = 9$), but others combined this with endemism or threats ($n = 8$, Table 1). Regardless of the number of species and criteria used for assessment, most previous research highlighted the same key regions as hotspots of marine biodiversity (Fig. 1).

The Coral Triangle (CT) is widely acknowledged as the center of marine biodiversity (Hoeksema, 2007; Barber, 2009; Bellwood and Meyer, 2009; Asaad et al., 2017) and was designated as a hotspot by the majority of reviewed literature ($n = 12$). It encompasses the seas around The Philippines, Indonesia, Papua New Guinea, Malaysia, The Solomon Islands, and Timor-Leste (Walton et al., 2014; Asaad et al., 2017). The CT harbors 76% of the world's zooxanthellate coral species (Veron et al., 2009a, b), more than 3250 reef fish species (Sanciango et al., 2013), six species of sea turtles (Asaad et al., 2018), more than 22 dolphin species (WWF, 2007), the highest richness of seagrass species (Spalding et al., 2003), and the largest mangrove forest in the world (Polidoro et al., 2010; Walton et al., 2014). As well as extraordinary levels of biodiversity, 225 million people live in the region (Veron et al., 2011) depending on the local marine ecosystems, habitats and species for their food and livelihood. Consequently, the human impacts on this region are likely severe (Veron et al., 2011) and given that Indo-Pacific reefs are declining each year (Bruno and Selig, 2007), make this a key marine biodiversity hotspot.

Geographically close to the Coral Triangle, another frequently stated hotspot from the literature ($n = 16$) are the waters of Japan, Taiwan and China. The upwelling of currents and variation in ocean temperatures make this hotspot highly biodiverse (Veron et al., 2011; Huang et al., 2015). The species richness of the region is influenced by the Kuroshio Current which increases larval dispersal from the CT northward as far as Japan (Veron et al., 2011). The literature shows that the waters of Japan and China are a global hotspot for cetacean species richness with >30 species, at least seven endemic, (Pompa et al., 2011). The South China Sea also has extraordinary coral diversity (571 known species Wu and Zhang, 2012; Huang et al., 2015). Additionally, Roberts et al. (2002) observed that South Japan harbored the highest levels of species endemism in their tropical study, highlighting the biological importance of this hotspot. The area is heavily impacted, with heavy fishing pressure, pollution, and dense human populations continuing to threaten the remaining marine biodiversity (Watson and Pauly, 2001; Daoji and Daler, 2004; Albouy et al., 2017).

Thirteen of the global studies reviewed included South Africa or the Eastern African region (countries including, South Africa, Mozambique, Madagascar, Kenya, Tanzania, Seychelles, and the South Mascarene Islands) as marine biodiversity hotspots. Eastern South Africa has particularly high species endemism (Roberts et al., 2002), while overall South Africa is a biodiversity hotspot for cetaceans (Pompa et al., 2011; Albouy et al., 2017) and sharks (Lucifora et al., 2011; Dulvy et al. 2014). Global studies show that the East African region has high species richness of reef fish (Stuart-Smith et al., 2013) and marine mammals (Albouy et al., 2017). Unfortunately, the marine biodiversity of Kenya, Tanzania, Mozambique and the Mascarene Islands is heavily impacted by overfishing and habitat degradation (Halpern et al., 2008), making it a hotspot for conservation.

Eleven studies located marine biodiversity hotspots in the Caribbean, Gulf of Mexico and South-Eastern United States (Table 1), regions that often showed overlap within the literature. Caribbean corals exhibit low coral species diversity, with the Mesoamerican barrier reef system home to just 65 species of scleractinian corals (Mission Blue, 2013), compared with the ≥ 600 species present in the CT (DeVantier and Turak, 2017). However, the high endemism of marine species (Roberts et al., 2002; Lucifora et al., 2011; Selig et al., 2014), increasing anthropogenic pressure on marine ecosystems (Hughes 1994; Hawkins and Roberts, 2004; Govers et al., 2014), historical and current large-scale coral bleaching events (Goreau, 1992; Wilkinson and Souter, 2008; Alemu and Clement, 2014), and a phase shift from coral dominated to macroalgal dominated reefs (Bruno et al., 2009; Arias-González et al., 2017), make the Caribbean an important hotspot for marine biodiversity and conservation efforts. Neighboring the Caribbean, the Gulf of Mexico is highly biodiverse (Costello et al., 2010). In addition to high species richness, the gulf is home to a variety of IUCN threatened species such as bluefin tuna (Endangered), which are known to spawn in the warm waters of the gulf (Teo et al. 2007); whale sharks (Endangered), which aggregate annually in their hundreds (Hueter et al., 2013), and five species of sea turtle (Valverde and Holzwart, 2017). The Gulf of Mexico is heavily impacted by overfishing, pollution and habitat loss, and biodiversity in the region is the second highest threatened globally after the Mediterranean (Costello et al., 2010). Adjacent to the gulf and the Caribbean, South-Eastern United States harbors high biodiversity of all taxa (Molinos et al., 2016), specifically high shark species richness and endemism (Lucifora et al., 2011), and fish species richness (Worm and Branch, 2012). This hotspot is also subject to overfishing and habitat loss and in need of prioritizing to protect marine biodiversity (Costello et al., 2010).

Table 1 Review of literature on global marine biodiversity hotspots.

<i>Author(s)</i>	<i>Species</i>	<i>Criteria</i>	<i>Hotspots</i>
Rutherford et al. (1999)	33 Species foraminifera	Species richness	Middle latitudes in all oceans
Roberts et al. (2002)	3235 species Reef fish, corals, snails, lobster	Species richness, endemism, human threats	Philippines; Gulf of Guinea; Sunda Islands; South Mascarene Islands; Eastern South Africa; North Indian Ocean; South Japan; Cape Verde Islands; West Caribbean; Red Sea
Worm et al. (2005)	15 Species ^a Tuna and billfish	Species richness	Clustered mostly in the subtropics: U.S. and Australian East Coasts; South of the Hawaiian Islands chain; East of Sri Lanka; most prominently in the South Eastern Pacific
Tittensor et al. (2010)	11,567 Species across 13 taxonomic groups ^b	Species richness	Philippines; Japan; China; Indonesia; Australia; India and Sri Lanka; South Africa; Caribbean and South West United States
Kaschner et al. (2011)	115 Species ^b Marine mammals	Species richness	New Zealand; Japan; Baja California; Galapagos Islands; the South East Pacific; the Southern Ocean
Lucifora et al. (2011)	507 Species ^b Sharks	Species richness, functional diversity, endemism	Japan; Taiwan; the East and West Coasts of Australia; South East Africa; South East Brazil; South East United States
Pompa et al. (2011)	123 Species ^b Marine mammals	Species richness, endemism, IUCN threat status	Baja California; Peru; North East America; Argentina; North West Africa; South Africa; Japan; Australia; New Zealand. Key marine endemism sites: Hawaiian Islands; Galápagos Islands; San Felix and Fernandez Islands; Mediterranean Sea, Kerguelen Island
Trebilco et al. (2011)	15 Species ^b Tuna and billfish	Species richness, human threats	US East Coast; South East Sri Lanka; Mauritius; Easter Island; Australia; Brazil; China; Costa Rica; El Salvador; India; Japan; Kenya; Nicaragua; Somalia; Tanzania
Worm and Branch (2012)	>4000 Species Fish	Species richness	Caribbean and South East United States; Western Central America; North East South America; Brazilian South East; North West Africa (Morocco, Western Sahara, Mauritania, Senegal); South Africa, Mozambique (Inc. Channel); Madagascar; Arabian Sea (Inc. Red Sea, Persian Gulf); Yellow Sea; East China Sea; South Japan; Taiwan; South China Sea; Indonesia; Philippines; Malaysia; North and East Australia
Jablonski et al. (2013)	5726 Species Bivalves	Species richness	Tropical West Pacific (Northern Australia, Indonesia, Malaysia, Philippines, Taiwan, China, Vietnam, Cambodia, Thailand)
Stuart-Smith et al. (2013)	2473 Species Reef fish	Species density, species evenness, functional group richness, functional diversity	West Indian Ocean (Mozambique, Tanzania Kenya, Madagascar, Seychelles, Mauritius, Reunion); Central Indian Ocean (Maldives, Chagos Archipelago); East Indian Ocean (Andaman Islands, Burma, Thailand); Central-Western Pacific Ocean (Indonesia, Malaysia, Philippines, New Guinea, Taiwan and south of Japan); North-East/West Australia; Central Pacific Ocean; India and Sri Lanka; Red Sea
Dulvy et al. (2014)	1041 Species ^b Chondrichthyans	Species richness, IUCN threat status, endemism	Indo-Pacific Biodiversity Triangle; Red Sea; Mediterranean Sea; Northern South America from Ecuador to Brazil including Panama; South East Brazil to South East Argentina; Togo, Benin, Nigeria, Cameroon, Equatorial Guinea and Northern Gabon; South Africa, Mozambique and East Madagascar; East Yemen and West Oman; Northern Persian Gulf; Northern Bay of Bengal and Andaman Sea; China, Taiwan, Vietnam and the Gulf of Thailand; North Australia; South and South East Australia; New Caledonia
Selig et al. (2014)	12,497 Species >21 phyla and 966 families ^b	Species richness, endemism, human threats	Australia; Indonesia; Antarctica; Russia; Japan; Philippines; Canada; Greece; Vietnam; Papua New Guinea; China; Taiwan; Egypt; Brazil; United States; Malaysia; Turkey; Mexico; Bahamas
Jenkins and Van Houtan (2016)	4352 Species	Species richness, endemism, human threats, IUCN threat status	Coral triangle, East Melanesia, Micronesia, Ryuku Archipelago, Caribbean, Sri Lanka, Red Sea, region of Madagascar
Molinos et al. (2016)	12,796 Species ^b	Species richness	Caribbean; Gulf of Mexico; South East United States; Mozambique; Tanzania; Kenya; Madagascar; India and Sri Lanka; Maldives; Chagos Archipelago; Andaman Islands; Burma; Thailand; Indonesia; Malaysia; Philippines; New Guinea; Taiwan; South Japan; Northern Australia; Central Pacific Ocean
Albouy et al. (2017)	121 Species ^b Marine mammals	Species richness, human threats	Baja California; Peru; Patagonian waters of Chile and Argentina; Uruguay; South East Brazil; Western Sahara; South Africa; Southern Mozambique; South Japan; Gulf of Thailand; Java Sea; Southern Australia, Tasman Sea; New Zealand

(Continued)

Table 1 (Continued)

Author(s)	Species	Criteria	Hotspots
Davidson and Dulvy (2017)	1007 Species ^b Chondrichthyans	Endemism, IUCN threat status	Argentina, Brazil, Uruguay, Chile, Colombia, South Africa, Mozambique, Indonesia, Philippines Taiwan China, Japan, Australia
Ramírez et al. (2017)	2183 Species ^b Fish, marine mammals, seabirds	Species richness	Peru and the Galápagos Archipelago; Patagonian waters of Argentina and Uruguay; West Indian Ocean (South Africa, Mozambique, Tanzania Kenya and Madagascar); Central-western Pacific Ocean (Indonesia, Malaysia, Philippines, New Guinea, Taiwan and south of Japan); New Zealand and East and South Australia; Oceania and central Pacific Ocean

Note the species analyzed in each study, the criteria used to assess sites and the designated hotspots.

^aValidated against total predator richness (145 species) from independent scientific observer data from the Atlantic and Pacific Ocean.

^bIndicates geographic scope is whole ocean.

Fig. 1 Centers of endemism as defined by the reviewed literature (circled) overlaid on species richness derived from modeled geographic ranges of 25,000 marine species from AquaMaps (Kaschner et al., 2016). Hotspots of both endemism and species richness are circled white.

In total, the literature lists more than 70 discrete marine biodiversity hotspots in the EEZs of more than 71 countries (Table 1), as well as in the High Seas (also called Areas Beyond National Jurisdiction, ABNJ). Species richness varied depending on the taxa studied, but generally peaked in Australia, South East Asia though to Japan, South Asia (India, Sri Lanka, Lakshadweep, Maldives, Chagos Archipelago), South East Africa, the Caribbean and South East United States (e.g., Tittensor et al., 2010; Worm and Branch, 2012; Stuart-Smith et al., 2013; Molinos et al., 2016). Endemism is higher in areas isolated by distance, notably Hawaii (Pompa et al., 2011), Easter Island (Roberts et al., 2002), and Antarctica (45% species endemic) and New Zealand (51%) (Costello et al., 2010). Endemism is also higher in areas with currents moving water from tropical to temperate regions, e.g., east and west coasts of Australia (Roberts et al., 2002; Selig et al., 2014; Davidson and Dulvy, 2017), South Africa (Pompa et al., 2011; Dulvy et al., 2014; Selig et al., 2014) and Japan (Lucifora et al., 2011; Selig et al., 2014; Davidson and Dulvy, 2017).

The literature that included human threats as an assessment criteria for hotspots ($n = 5$) used threats and human impacts derived from either Halpern et al. (2008), a synthesis of 17 anthropogenic drivers of change; or Bryant et al. (1998), a map based indicator of threats to coral reefs based on coastal development, overexploitation, and pollution. Halpern et al. (2008) showed medium to high impact in all areas designated by the literature as areas of high species richness, while Bryant et al. (1998) assigned a local threat level for coral reefs as either high or very high for the majority of Caribbean and CT reef systems. In addition to human threat and risk indicators, the literature has used IUCN species status to determine at risk species (e.g., Pompa et al., 2011; Dulvy et al., 2014; Jenkins and Van Houtan, 2016; Davidson and Dulvy, 2017), with threatened species richness and endemism mapped in order to prioritize the protection of imperiled species (Dulvy et al., 2014). Three of the four studies that included threatened endemic species, showed hotspots overlapping with those of global species richness and endemism. The remaining study (Pompa et al., 2011) focussed solely on marine mammals, which have high species richness in the southern hemisphere and contrasting distributions to other marine taxa (Kaschner et al., 2011; Albouy et al., 2017).

Fig. 1 shows that areas of high species richness often correspond with high species endemism, but areas of high endemism are also often distinct to areas of high species richness. Examples of high endemism and low species richness include the Gulf of California, South East Brazil, South Africa, Southern Mozambique and the Red Sea, among others, as well as islands and archipelagos such as Hawaii, Easter Island, St Helena and Ascension Islands, Cape Verde Islands, the Mascarene Islands and New Zealand, which typically have lower species richness and higher species endemism due to isolation (Costello et al., 2017). Although Antarctica has high endemism, it is generally excluded as a hotspot because it is relatively species poor when compared to the tropics (Costello et al., 2010) and was only included by one study (Selig et al., 2014). The “hottest” hotspots, areas of high endemism and species richness, are in the West Caribbean, South Madagascar, Chagos Islands, Maldives, Lakshadweep, Sri Lanka, South Japan, East China Sea including Taiwan, Coral Triangle, New Caledonia, Vanuatu and North East and North West Australia (Fig. 1).

Methods of Mapping Hotspots

The literature has used a variety of data sources to map global marine species distributions and threats to biodiversity (Table 2). Studies have compiled extensive data from previous research, opinion sources, fishing records and site surveys, as well as using

Table 2 Data used to determine marine biodiversity hotspots.

Author(s)	Primary data	Supplementary data
Rutherford et al. (1999)	Planktonic foraminifera database—from surface-sediment samples	Sea surface temperature satellite data
Roberts et al. (2002)	Expert opinion, museum records, literature sources, monographs, loan specimens, and extensive personal observations by author(s)	Bryant et al. (1998)—threats to coral reefs based on observational and objective data
Worm et al. (2005)	Fishery records—Japanese longline data (1990–99) ^a	Independent scientific observer data from Atlantic and Pacific longline fisheries
Tittensor et al. (2010)	Ocean Biogeographic Information System (OBIS)	Expert verified range maps and empirical occurrence data
Kaschner et al. (2011)	Relative Environmental Suitability (RES) model—based on expert knowledge, literature and occurrence data	
Lucifora et al. (2011)	Expert knowledge from literature sources and fishery reports	Global Biodiversity Information Facility (GBIF) occurrence records—where supported by literature
Pompa et al. (2011)	Literature sources—objective and observational data	International Union for Conservation of Nature (IUCN)—threat status
Trebilco et al. (2011)	Fishery records—Japanese longline data (1990–99) ^a	Halpern et al. (2008)—Human impacts based on observational and objective data
Worm and Branch (2012)	FishBase—based on objective and observational data, expert opinion and literature sources	Sea Around Us Project data, based on fishery records, numerous other databases and literature
Jablonski et al. (2013)	Literature, museum specimens, expert opinion, and occurrence data	
Stuart-Smith et al. (2013)	Reef Life Survey data—based on observational occurrence records	FishBase and authors' expert knowledge of species
Dulvy et al. (2014)	Expert opinion, literature sources, observational occurrence records	IUCN threat status, Food and Agriculture Organization (FAO) landing records
Selig et al. (2014)	Expert opinion, AquaMaps—predicted distributions based on occurrence data and expert opinion, BirdLife International—distributions based on objective and observational data	Halpern et al. (2008)—Human impacts
Jenkins and Van Houtan (2016)	IUCN species range maps—based on objective expert opinion and literature, BirdLife International, NatureServe and State of the World's Sea Turtles—both based on observational occurrence records and expert opinion	Halpern et al. (2008)—Human impacts, IUCN threat status
Molinos et al. (2016)	AquaMaps	
Albouy et al. (2017)	IUCN species range maps	Halpern et al. (2008)—Human impacts
Davidson and Dulvy (2017)	Expert opinion, literature sources, observational occurrence records	IUCN threat status
Ramírez et al. (2017)	IUCN species range maps, BirdLife International species distributions	FAO—FishStatJ

Data sources show variation within the literature, with studies using objective and observational data as the primary basis for species distribution analyses.

^aValidated against total predator richness (145 species) from independent scientific observer data from the Atlantic and Pacific Ocean.

environmental envelopes, derived from occurrence data and known habitat use, to model distributions for species groups and individual taxa (Kaschner et al., 2011; Selig et al., 2014; Molinos et al., 2016). This data has then been used to assess a variety of criteria for measuring “diversity,” including species richness (all but Davidson and Dulvy, 2017), functional diversity (Lucifora et al., 2011; Stuart-Smith et al., 2013; Albouy et al., 2017), phylogenetic diversity (Albouy et al., 2017), functional richness (Lucifora et al., 2011; Stuart-Smith et al., 2013; Albouy et al., 2017), and how evenly distributed individual abundances were between species (Stuart-Smith et al., 2013). The chosen species diversity criteria were then mapped, along with any further data such as threat level and endemism, and those mapped cells that represented the highest proportions of the selected criteria were deemed hotspots of marine biodiversity. Worm et al. (2005) and Trebilco et al. (2011) selected the 50 cells with the highest values for species richness and/or diversity. Albouy et al. (2017) defined hotspots as “all grid cells with values in the upper 2.5 % and 5 % of the biodiversity facet and human threat value distributions,” while Ramírez et al. (2017) highlighted hotspots as those cells with species richness above the upper 95th percentile.

Of the seven studies to include endemism, Jenkins and Van Houtan (2016) defined endemic species as those species classed as “small-ranged” by the IUCN, species with ranges smaller than the global median for that taxon (Jenkins et al., 2015). All other studies used their own metrics of endemism. Roberts et al. (2002) defined marine biodiversity hotspots as centers of endemism with a medium to high level of threat from human activities, as defined by Bryant et al. (1998). They calculated areas of high species richness by mapping the geographic ranges of species and plotting the top 10% of cells with most species for each taxon. To assess endemism, they calculated range rarity as the reciprocal of range size, summed across species present (Roberts et al., 2002), and mapped the top scoring 10% of cells for each taxon. Cells in the top 10% for at least two taxa, added with any adjacent cells in the top 5% for any single taxa, were defined as multitaxon centers of endemism. Additionally, centers of endemism, cells with the top 5% for 1 taxon and 20% for two or more taxa were also included, resulting in 18 centers of endemism. They then calculated the number of restricted-range species, range ≤ 10 cells (500,000 km²), within each center of endemism and ranked sites according to the number of restricted-range species present. Although this method of defining marine biodiversity hotspots does not use species richness, range-rarity and species richness were shown to be closely coupled for corals (Roberts et al., 2002). This means that prioritizing hotspots as defined by Roberts et al. (2002) would benefit coral diversity, but may prove less beneficial for noncoral associated taxa (Roberts et al., 2002). However, their strategy was effective for species representation, with the 18 centers of tropical endemism including 74–96% of all species studied (Roberts et al., 2002).

Selig et al. (2014) used two measures of endemism, range rarity, areas with the greatest concentrations of relatively rare or range-restricted species, and proportional range rarity, areas with restricted range species, regardless of the number of species (range rarity/species richness). For diversity metrics (species richness, rarity and proportional range rarity) they identified the 5% of grid cells within the total area of EEZs and ABNJ that had the highest values. Using an area threshold ensured that each diversity metric contributed an equal area to the assignment of priorities (Selig et al., 2014). A 10% area threshold for human impacts was used because a 5% area was deemed too restrictive for overlap with other metrics and 10% was deemed beneficial for assessing broad scale management impacts (Selig et al., 2014). Consequently, 10% of the highest and lowest impacted EEZs and ABNJ were identified. Priority areas were then defined based on overlap between these diversity metrics and areas of high or low human impact. This technique ensures that areas with high endemism and species richness that are both heavily impacted and relatively pristine will be deemed as hotspots.

Pompa et al. (2011) used political endemism, that is species with a range restricted to a single country. They compiled species richness of marine mammals by mapping geographic range, and created a presence and absence matrix to tally the number of species present in each cell. Key conservation sites were then determined as either the 2.5% of cells with the highest species richness or as those with endemic species. This method of analyzing endemism was efficient at targeting single species such as the Hawaiian monk seal, Australian sea lion and vaquita, species that their respective country's may take an active interest in conserving (Pompa et al., 2011). However, many marine mammals are highly mobile, migratory, and do not observe state boundaries. Consequently, species endemic to ecosystems, regions and biogeographic realms, such as the finless porpoise, endemic to the waters of southern Japan and eastern China, will not be deemed priority species through this assessment.

Lucifora et al. (2011) defined marine biodiversity hotspots as those cells with at least the 95th percentile of shark species richness or endemism. Endemism was estimated for each cell as the sum of the inverse of the range of the species present in that cell (as in Roberts et al., 2002), with range defined as the number of cells a species occurred in. Cells were grouped according to their similarity of shark species composition, resulting in 93 biogeographic units. These units varied in size from 2 to 9645 1-degree latitude-longitude cells with similar assemblages (Lucifora et al., 2011). The cells with the highest number of species and highest number of endemic species were then identified in each unit, resulting in priority areas for all shark communities. Hotspots of shark species richness and endemism were shown in Indonesia, China, and Sri Lanka (Lucifora et al., 2011). These countries have the largest shark harvests in the world (Lack and Sant, 2011; Davidson et al., 2016), but the study did not include a threat index, and consequently did not prioritize shark biodiversity hotspots for protection.

Dulvy et al. (2014) defined endemic chondrichthyans (cartilaginous sharks, rays and their relatives) as those species with an extent of occurrence less than 500,000 km². The cells containing the highest number of IUCN threatened endemic species were called “Irreplaceability Hotspots.” Irreplaceability was calculated as the sum of the inverse of the geographic range of all threatened endemic species in a cell. Consequently, a cell value of 0.1 would represent 10% of a threatened endemic species' total global range. In total this resulted in 15 Irreplaceability Hotspots that harbored 66 threatened and endemic chondrichthyans (Dulvy et al., 2014). They also mapped species richness and threats, finding that areas of greatest species richness coincided with areas of most threatened

species (Dulvy et al., 2014). In addition to using IUCN species classifications, threatened species were categorized by habitat, enabling a comparison of species from coastal and continental shelf, neritic and epipelagic, deep-water and mesopelagic habitats.

Davidson and Dulvy (2017) determined endemism as those species with range areas less than or equal to the 50th percentile (595,749 km²) of extent of their geographic range, resulting in 99 imperiled and endemic chondrichthyan species. Hotspots were then defined by counting the number of imperiled endemic species in each hexagonal grid cell (23,322 km²) within each EEZ. This analysis resulted in the majority of hotspots being located in EEZs, with only five hotspot cells in ABNJ.

Application in Marine and Terrestrial Environments

The concepts used to define marine biodiversity hotspots are similar to those used in terrestrial environments. Myers et al. (2000) designated 25 terrestrial biodiversity hotspots driven by two criteria, endemic species, and threats. They based endemism principally on species of vascular plants, as their presence is critical to almost all forms of animal life (Myers et al., 2000), with an area needing to contain at least 1500 of the world's 300,000 species (0.5%) as endemics. The second basis, threats, necessitates that a hotspot of endemism should have lost $\geq 70\%$ of its primary vegetation. A similar approach was followed by Roberts et al. (2002) who identified tropical reefs as the most important areas for marine biodiversity, and used endemism and threats as the principle criteria for hotspot selection.

As in the marine realm, there have been numerous terrestrial studies focusing on individual taxa. Ceballos and Ehrlich (2006) mapped terrestrial mammal biodiversity hotspots using species richness, endemism and threat to extinction. They mapped species geographic ranges, counting the number of species present in each cell to attain species richness, a technique used in marine studies by Lucifora et al. (2011) and Pompa et al. (2011) among others. Endemic species were classified as those in each cell with a range $\leq 250,000$ km², and threatened species were those within each cell considered to be threatened, endangered or critically endangered by the IUCN. They then deemed cells to be hotspots by combining the top 2.5% and 5% of each category. Orme et al. (2005) identified bird breeding hotspots based on species richness, endemism, and threat. As in other terrestrial and marine studies, species richness was a count of the total number of species in each grid cell based on known ranges, threat was determined as those species in each cell that were deemed as threatened (BirdLife International, 2000), and endemism was defined as those species with restricted ranges, in this case those with a range of < 30 grid cells. Hotspots were then defined as the richest 2.5% of cells for each criterion. Finally, the congruence of hotspot cells were measured, resulting in 32 grid cells common to all hotspot types (Orme et al., 2005). Although this method analyzed the congruence of hotspots, the methods used to delineate biodiversity hotspots are conceptually the same as those used for various terrestrial and marine assessments (Myers et al., 2000; Roberts et al., 2002; Trebilco et al., 2011; Albouy et al., 2017).

The methods used for defining marine and terrestrial biodiversity hotspots have also been used in freshwater biodiversity hotspot analyses (Groombridge and Jenkins, 1998; Oberdorff et al., 2011; Tedesco et al., 2012; Collen et al., 2014). Species richness was calculated as the number of species per cell (Collen et al., 2014), endemism as species inhabiting a single drainage basin (Tedesco et al., 2012; Abell et al., 2008) or those with geographically restricted ranges, e.g., ranges in the lower quartile of a taxon (Collen et al., 2014). Threat was based on the distribution of IUCN threatened species (Collen et al., 2014), or analysis using Vörösmarty et al.'s (2010) global map of threats to freshwater biodiversity, a synthesis of 23 environmental impact stressors. Typically the 5% highest scoring cells of each parameter (Collen et al., 2014), or countries with the highest total counts (Tedesco et al., 2012), were then used to prioritize areas as hotspots of freshwater biodiversity (Collen et al., 2014). Whether in the marine, terrestrial or freshwater environment, the methods used to delineate sites are comparable between species groups, diversity indices and environments, providing a logical, universal approach to prioritize and subsequently protect biodiversity hotspots.

Discussion

The criteria outlined by Myers (1988) and used in the subsequent literature to designate marine biodiversity hotspots have been used both as single indices (Rutherford et al., 1999; Worm and Branch 2012; Ramírez et al., 2017) and collectively (Lucifora et al., 2011; Trebilco et al., 2011; Dulvy et al., 2014) to prioritize more than 70 sites for conservation (Table 1). When analyzing the distribution of marine species, endemic species and threats, it is clear that protecting hotspots of marine biodiversity should be viewed as the first step to ensuring the ecological integrity of our oceans, but will not be an effective strategy to represent and protect all marine life. Despite similarities, the distribution of marine species richness shows variations between taxa (Tittensor et al., 2010). Marine mammals display higher species richness in mid-southern latitudes (Pompa et al., 2011; Kaschner et al., 2011; Albouy et al., 2017), sharks, skates, rays and chimaeras have higher species richness along continental shelves (Lucifora et al., 2011; Dulvy et al., 2014), and some pelagic species show higher species richness in the open ocean (Worm et al., 2005). Moreover, fishes are one of the most intensively studied marine taxonomic groups (Eschmeyer et al., 2010), making up 24% (5877) of the 25,000 marine species with modeled distributions on AquaMaps (Kaschner et al., 2016). Considering that marine mammal and chondrichthyan species combined represent 1136 (Pompa et al., 2011; Davidson and Dulvy, 2017) of the 240,000 described marine species (Costello et al., 2013), and that reef fish alone outnumber these groups, ~ 4500 species (Froese and Pauly, 2014), identifying and protecting marine hotspots using species richness will not represent all marine taxa. How representative hotspots based on vertebrates are of all marine species is not yet known.

In addition to variations in marine taxa distributions, many centers of endemism are distinct from areas of high species richness (Fig. 1). Thus prioritizing hotspots of biodiversity based on Myers' criteria alone will leave centers of high endemism but low species richness unprotected. Endemic species contribute significantly to global biodiversity (Kosaki et al., 2017), but are more vulnerable to extinction due to their restricted ranges (Roberts et al., 2002). Furthermore, the distribution of endemic species is not always congruent between taxa, with shark (Lucifora et al., 2011; Dulvy et al., 2014), marine mammal (Pompa et al., 2011), and seabird species (Croxall et al., 2012) known to have discrete distributions, as well as overlapping areas of endemism. In the terrestrial realm, areas of high species richness often correlate with areas of high species endemism (Caldecott et al., 1996; Myers et al., 2000). However, as in the marine realm, there are also centers of endemism in isolated terrestrial areas that have low species richness (Caldecott et al., 1996; Kier et al., 2009). For example, islands are recognized as global centers of endemism (Kier et al., 2009) despite island species richness being generally lower than mainland sites (Whittaker and Fernández-Palacios, 2007; Kreft et al., 2008). Additionally, terrestrial areas of endemism differ between taxa, as shown by Kier et al. (2009) who found that when comparing the top 30 regions of plant endemism richness, amphibian endemism shared 49% of range equivalents but mammals only 32%. In freshwater environments, areas of high species richness are congruent with areas of high numbers of endemic species. However, the percentage of freshwater endemic species is greater in isolated areas, showing substantial centers of endemism in areas inside and outside the tropics (Tedesco et al., 2012; Abell et al., 2008). Patterns of freshwater endemism and species richness also lack congruence among taxa, as shown by Collen et al. (2014) who compared the distribution of freshwater amphibians, reptiles, mammals, crabs, fishes, and crayfish.

From global assessments of species endemism in marine, freshwater and terrestrial environments, it is clear that hotspots of endemism are both congruent with, and distinct from areas of high species richness. The IUCN use endemism as a criterion to identify conservation areas instead of species richness (Asaad et al., 2017). By doing so they aim to protect the ranges of endemic species as well as more common species that may have overlapping distributions. Regardless of the criteria preferred, in order to effectively prioritize and protect marine biodiversity, both global and regional scale assessments of endemism between groups and individual species are necessary.

Myers' criteria for designating hotspots requires that areas be under exceptional degrees of threat. This criterion enables biodiverse areas to be urgently prioritized before they are lost to exploitation and destructive practices, and is defined as areas that have lost $\geq 70\%$ of primary vegetation (Myers, 1988). In the marine realm, habitat loss is difficult to quantify, requiring well planned monitoring (Airolidi et al., 2008) and the extent of some habitats, such as mesophotic coral reefs, is only now beginning to emerge (Lesser et al., 2009; Bridge et al., 2013; Laverick and Rogers, 2019). Five studies used threats as a parameter for designating areas as marine biodiversity hotspots (Table 1). However, by using threat analyses to define marine biodiversity hotspots, we may exclude high biodiversity areas that are unthreatened or no longer threatened. Coral reefs harbor one third of all described marine species (Reaka-Kudla, 2001; Costello, 2015) and cover just 0.2% of the marine environment (Veron et al., 2009a,b), but coral reefs worldwide are under varying degrees of threat (Carpenter et al., 2008). Rather than only deeming threatened coral reef ecosystems as marine biodiversity hotspots, all areas with the richest and most unique biodiversity should be prioritized. Moreover, due to the increasing global scale impact of anthropogenic stressors, such as climate change induced ocean warming and acidification (Costello et al., 2013; Rodgers et al., 2018), as well as continued unsustainable and destructive fishing practices (Petrossian, 2015; Rhodes et al., 2018), it could be argued that all marine habitats and species are under threat. Consequently, designating hotspots based on species richness and endemism alone represents a more efficient approach to target and conserve marine biodiversity.

The aim of Myers' (1988) hotspot analysis was to enable a 'silver bullet' strategy to combat biodiversity loss and target conservation resources where they were needed most. It garnered worldwide interest, generating more than \$ 750 million USD of funding support, the largest sum ever assigned to a conservation strategy (Myers and Worm, 2003), and has since been used extensively in marine, terrestrial and freshwater conservation planning. Defining biodiversity hotspots has helped lead to the protection of 15% of terrestrial environments (Gray et al., 2016; Jones et al., 2018), but to date less than 5% of the world's oceans are afforded some form of protection. Additionally, just 2% of the ocean is designated as no-take marine reserves (Marine Conservation Institute, 2019), the most effective type of marine protected area (Lester and Halpern, 2008; Costello and Ballantine, 2015). Myers' approach has been used extensively, and over the last 30 years the term hotspots has evolved to pertain to areas of high species richness, or areas of high endemism, that may or may not be under high threat. The data used to underpin hotspot analyses has also evolved from objective and observational data to modeled and observational data sources, enabling the prediction of species distributions under altering climatic variables and threats (Kaschner et al., 2011; Molinos et al., 2016; Ramírez et al., 2017).

Threatened species, which may have reduced genetic diversity (Phillips et al., 2011; Evans et al., 2014), may be subject to higher human exploitation and habitat loss (Dulvy et al., 2014), and frequently have restricted ranges (Gales and Fletcher, 1999; Hawkins et al., 2000). Due to their increased vulnerability they must be prioritized for protection, yet these species are not necessarily included in global scale hotspot analyses. In total the IUCN has assessed 987 marine species as threatened (IUCN, 2019) (i.e., Critically Endangered, Endangered or Vulnerable), but many more are data deficient (DD) and likely threatened (Dulvy et al., 2014; Jarić et al., 2016; Jenkins and Van Houtan, 2016; Roberts et al., 2016) (Fig. 2). Just four studies acknowledge the importance of protecting IUCN threatened species by including IUCN status in their biodiversity hotspot assessments (Pompa et al., 2011; Dulvy et al., 2014; Jenkins and Van Houtan, 2016; Davidson and Dulvy, 2017). Only by protecting biodiversity hotspots of species richness, centers of endemism and threatened species can we reduce the global risk of species extinction, support species recovery (Ardron et al., 2009) and protect marine biodiversity.

Fig. 2 Percentages of marine species groups assessed as not threatened (white bar), Threatened (black), and data deficient (gray) by the IUCN. Overall species (12,748), Mollusca (1374), Echinodermata (362), Reptilia (69), Chondrichthyes (1083), Actinopterygii (7957), Cnidaria (879), Arthropoda (254), Marine mammals (128), and Seabirds (346). All data from the IUCN Red List (IUCN, 2019), correct on 01/05/19.

Acknowledgments

Tamlin Jefferson is very grateful to be the recipient of the Commonwealth Scholarship, and the Stanley Wishart Low Memorial Scholarship in Marine Science.

Glossary

Ancestral gene order To date six different mitochondrial gene orders have been found in the subclass Octocorallia. The mitochondrial gene arrangement shared by the octocoral common ancestor is considered the ancestral one.

Anthocodia The distal part of a polyp, bearing the mouth and the tentacles; in many cases it can be retracted within the calyx, the stem, the branch or within the cortex.

Apomorphy A character derived/changed from the form found in the ancestor.

Aragonite skeleton Aragonite is a carbonate mineral, one of the three most common naturally occurring crystal forms of calcium carbonate (CaCO_3), the other forms are the minerals calcite and vaterite.

Autozoid Autozooids are one of the five polyp types in octocorals, and the main function of autozooids is to gather food with their tentacles and make sure it gets to the mouth of the autozoid polyp.

Clade Characters or traits that are derived from ancestral characters over evolutionary history or organisms which share a common ancestor are grouped into the same clade. A clade is monophyletic by definition.

Dynamite fishing Also known as blast fishing is the practice of using explosives to stun or kill schools of fish for easy collection. This is often illegal and can be extremely destructive to the surrounding ecosystem, as the explosion often destroys the underlying habitat (such as coral reefs).

Epibiont An epibiont (from the ancient Greek meaning "living on top of") is an organism that lives on the surface of another living organism and is harmless to its host.

Exon loci Specific traits of a gene at certain positions on the chromosome.

Gastrovascular or gastric cavity Also, coelenteron, the interior space of a polyp.

Gene order The arrangement of the genes into a given genome.

High-throughput sequencing In molecular biology, a technology which allows to sequence on large scales and simultaneously multiple DNA molecules.

Indel-rich In molecular biology, INDELs refer to mutation/recombination events that occur in the genome of a given organism. Such mutations can be either insertions or deletions.

Marine Natural Products (MNP) Natural compounds produced by marine organisms which have potential economic and commercial value.

Mitogenome Small fraction of the total DNA that is contained in the mitochondria. Animal mitogenomes typically harbor 13 protein-coding genes, two ribosomal RNA genes and 22 transfer RNA genes. Variations in terms of gene content and genome size may occur in some non-bilaterian metazoans.

Monogeneric In taxonomy monogeneric refers to a group that includes a single genus.

Monophyletic group In phylogenetics a group of organisms that share the most recent common ancestor.

Ovulids (Ovulidae) A common name for members of the family Ovulidae, other common names are cowry allies or false cowries. Ovulidae is a family of small to large predatory or parasitic sea snails, marine gastropod molluscs.

Paraphyletic group In phylogenetics is a group of organisms which include the most recent common ancestor but a few of its descendant.

Pharynx Tubular passageway between the mouth and the gastric cavity in octocoral polyps.

Pinnule The lateral processes of a tentacle.

Polyp leaves The flattened expansions bearing the secondary polyps in some Pennatulacea.

Polyphyletic group In phylogenetics a group of organisms derived from more than one ancestor.

Predator An organism that preys upon other organisms.

Prostaglandines A group of physiologically active lipid compounds that have various hormone-like functions (regulating inflammation, blood flow, etc.).

RAD-Seq Restriction site Associated DNA Sequencing (RAD-Seq) is a fractional genome sequencing strategy. By digesting the genome with a restriction nuclease and attaching a series of adapters to the resulting DNA fragments, large numbers of genetic variations such as SNPs can be readily identified from analysis of next generation DNA sequence data.

Sanger sequencing Method of DNA sequencing based on selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication.

Sclerite A calcareous element, irrespective of form, in the mesoglea. Also occurring in the axis of Scleraxonia. There are many different forms of sclerites (Fig. 2B).

Siphonoglyph (sulcus) The strongly ciliated groove extending down one side of the pharynx.

Stolon Rounded or flattened elongate or membranous coenenchyma expansion growing over or into the substrate and peripherally producing new polyps.

Stolonifera A subordinal grouping within the Alcyonacea, characterized by the colony growth form of polyps connected through stolons.

Subordinal group Taxonomic entity just below the order rank; this rank is not recognized by some taxonomists.

Synapomorphy Refers to derived characters of a clade. A synapomorphy is a shared apomorphy that distinguishes a clade from other organisms.

Topological incongruences When phylogenetic relationships among taxa are not consistent in the phylogenetic trees obtained using different methods.

Ultra-conserved elements Portion of the DNA regions that are highly conserved among different species/lineages.

Vagile Free to move about.

Abstract

Shallow water tropical and subtropical coral reef communities are among the most species rich habitats of the world. Among these coral reefs, octocorals are common members of invertebrate reef fauna. The ecological importance of octocorals can be seen through their use as microhabitats by marine vertebrates and invertebrates (e.g., shrimp, fish, ovulids); acting as important spawning, nursery, breeding and feeding areas for a variety of other organisms, and additionally providing refuge from predators. Therefore, their three-dimensional structures contribute to the structural complexity and biodiversity of reefs, facilitating niche diversification, and speciation. Despite their importance to reef ecology and biodiversity, octocorals have received relatively little attention, compared to other anthozoan groups such as scleractinian corals, and thus remain a poorly known and little-studied group. However, as their abundances increase due to the decline of scleractinian corals worldwide, octocorals are likely to play a growing role in future reefs. The purpose of this review is thus to gather existing knowledge on their biology, ecology and societal importance in order to provide a comprehensive information source for future research efforts.

Systematics and Taxonomy

Octocorallia Haeckel, 1866 is a subclass within Anthozoa Ehrenberg, 1834, phylum Cnidaria Verrill, 1865, and its members have been reported worldwide (Van de Water et al., 2018). Octocorals are found in many marine environments and are most diverse and conspicuous on tropical and subtropical shallow reefs and in deep-sea environments, where they are often dominant space-occupiers and important structural components of the benthic community (McFadden et al., 2010). There are approximately 3500 species of soft corals, gorgonians, and sea pens described, which belong to ca. 378 octocoral genera from 55 families (Daly et al., 2007; McFadden et al., 2010; Williams and Cairns, 2018), with new species, genera (e.g., Benayahu et al., 2017a,b; Conti-Jerpe and Freshwater, 2017; Lau et al., 2018, 2019; Lau and Reimer, 2019) and even families (McFadden and van Ofwegen, 2012; Breedy et al., 2012) continuing to be described. This is especially true for environments in deep-sea and in the shallow coral reefs of the Indo-Pacific, where the highest diversity of octocorals is observed (Pérez et al., 2016). Octocorallia currently has three orders (Alcyonacea, Helioporacea and Pennatulacea). Helioporacea (blue corals) and Pennatulacea (sea pens) are the only orders with well-defined synapomorphies; blue corals due to their massive aragonite skeleton, and sea pens for the presence of a proximal peduncle used for anchorage in the substrate (McFadden et al., 2010; Goffredo and Dubinsky, 2016). Bayer (1981) merged the remaining four orders into Alcyonacea, which comprises stoloniferous forms, soft corals, and gorgonians, and this scheme is

currently followed by most taxonomists. However, Alcyonacea is still considered unstable along with many family-level classifications (McFadden et al., 2006, 2010).

The sea pens, order Pennatulacea Verrill, 1865, comprise 14 families, 37 genera, and over 200 species (Williams, 2011; McFadden et al., 2010; García-Cárdenas et al., 2019; Kushida and Reimer, 2019) (Fig. 1A). Two suborders, Sessiliflorae Kükenthal, 1915 and Subsessiliflorae Kükenthal, 1915, were established in the early 20th Century, which some classification systems still use in the present day (Cordeiro et al., 2019a). Sessiliflorae have autozooids arising directly from the rachis, whereas Subsessiliflorae have polyps connected on polyp leaves (Kükenthal and Broch, 1911, Kükenthal, 1915, Imahara et al., 2014, Cordeiro et al. 2019). Further morphological and cladistical investigations into the classification system of Pennatulacea proposed by Kükenthal and Broch (1911) and Kükenthal (1915) highlighted the paraphyly of Sessiliflorae and monophyly of Subsessiliflorae (Williams, 1995; Kushida and Reimer, 2019). The difficulties encountered so far are most likely due to sampling efforts, the paucity of morphological characters, and high intraspecific variability (Williams, 1992). To date molecular phylogenetic reconstructions by Dolan et al. (2013) and Kushida and Reimer (2019) strongly reject the monophyly of the two suborders. Most recently, Hogan et al. (2019) sequenced the complete mitogenome of deep-sea sea pens and found at least three different mitogenome arrangements within Pennatulacea, including one novel gene order. Besides from the ancestral gene order (Beagley et al., 1995; Brockman and McFadden, 2012) that is the most common among octocorals, the bamboo coral genus *Acanella* and a member of family Keratoisidinae have differing mitochondrial gene orders (Brugler and France, 2008). As well, the sea pen *Umbellula* has been reported to have a novel gene arrangement for octocorals (Hogan et al., 2019).

The order Helioporacea Bock, 1938 comprises only two families, Helioporidae Moseley, 1876 and Lithotelestidae Bayer & Musik, 1977. Members of Helioporacea produce a solid matrix forming a crystalline aragonite skeleton, which is considered a unique feature among octocorals (McFadden et al., 2010). The family Helioporidae is monogeneric, represented by two valid species within the extant genus *Heliopora* Blainville, 1830, (Fig. 1B and D) and it is most well-known for the blue coral *Heliopora coerulea* (Pallas, 1766). Recently, a second valid species, *Heliopora hiberniana* Richards et al., 2018 was described from northern Western Australia. Unlike *H. coerulea*, some individuals of *H. hiberniana* feature a white skeleton, thus displacing the most diagnostic and conserved character within the genus *Heliopora*—the blue skeleton (Richards et al., 2018). The family Lithotelestidae includes only two genera, *Epiphaxum* Lonsdale, 1850 (Bayer, 1992), with two extant species reported from the deep seas of the western Atlantic and the western Indian Oceans (50–400 m), and *Nanipora* Miyazaki & Reimer, 2015, found from several shallow locations in the western Pacific, including Thailand, Okinawa, and Dongsha Atoll (Miyazaki and Reimer, 2015; Miyazaki et al., 2016; Plaza et al., 2017; Reimer et al., 2017). Unexpectedly, *Nanipora* has been found in seagrass beds along the northwestern coast of Dongsha Island with unusual colony forms; either forming hollow rounded mounds, unattached to any other organism, or encrusting other organisms, such as seagrass stem bases, sponges, and dead scleractinian corals (Reimer et al., 2017) (Fig. 1E).

All other remaining octocoral species belong to the order Alcyonacea Lamouroux, 1816, which is thus the most diverse order in terms of species number. This order includes ~31 families of soft corals and sea fans (Fig. 1C and F–J), and lacks any defining synapomorphies (Daly et al., 2007; McFadden et al., 2010). Members of this order have been divided into sub-ordinal groups Alcyoniina, Calcaxonia, Holaxonia, Protoalcyonaria, Scleraxonia, and Stolonifera, however this classification is not supported by molecular analyses and is acknowledged to reflect morphological categories rather than clades (Bernston et al., 2001; McFadden et al., 2006, 2010; Cordeiro et al., 2019b).

Despite their high diversity, only about 25% of the described octocoral species are found in waters shallower than 50 m (Williams and Cairns, 2015; Pérez et al., 2016). Each subordinal group includes shallow water octocorals, yet most of the species inhabiting coral reef communities are alcyoniids. *Lobophytum* Marenzeller, 1886, *Sinularia* May 1898 and *Sarcophyton* Lesson, 1834 are considered among the most important contributors to the total biomass of Indo-Pacific reefs, covering up to a quarter of the reef surface (Dinesen, 1983; Fabricius and Alderslade, 2001). Members of Calcaxonia, Holaxonia and Scleraxonia, also known as gorgonians, are commonly distributed in worldwide coral reefs, and are particularly diverse and abundant in the Caribbean (Bayer, 1961). Similar to soft corals and sea fans, stoloniferans can be found at various depths and latitudes (Daly et al., 2007; McFadden and van Ofwegen, 2012). Among them, *Tubipora musica*, the only known reef-building alcyonarian species (Fig. 1I and J), contributes to the benthic coverage of Indo-Pacific reefs, and can reach relatively high coverages (up to 28%) at some Western Australia locations (Richards et al., 2013).

Biology and Morphology

As the name octocoral suggests (from Latin “octo”), the sessile, mostly colonial Octocorallia are composed of polyps with eight tentacles (almost always pinnate) and eight mesenteries (divisions in the body cavity), characters that are invariant within the clade (Daly et al., 2007).

In octocorals, the polyp is the individual zooid and together the polyps are responsible for all the vital functions of the colony (e.g., growth, food capture, transport of nutrients, irrigation with seawater, defense and reproduction). Most octocoral species have a single type of polyp (the autozooid) and are monomorphic. Species in some groups, such as sea pens, have a second type of polyp (the siphonozooid), and thus are dimorphic. The siphonozooid may either have one rudimentary tentacle or none at all and their function is to transport water, supporting the hydroskeletal system of the colony. In general, the term “polyp” refers to sexual individuals, the autozooids (Bayer, 1973; Fabricius and Alderslade, 2001; Samimi-Nami and Ofwegen, 2012). Oozooids, which are single primary polyps located at the center of the colony, are exclusively known from sea pens. However, other types of polyps

Photograph: YW Lau.

such as mesozooids or acrozooids can also be observed in some Pennatulaceans (Williams, 2011; Williams et al., 2012). Recently, a fifth type of polyp, the acrozooid, was described in two *Pteroeides* species from the tropical western Pacific coral reef regions (Williams et al., 2012).

The polyp is a tubular structure, consisting of two main parts. The upper end (anthocodia) is contractile, extends above the colony surface and has a central mouth opening surrounded by eight tentacles. The tentacles have finger-like extensions (pinnules) along each side, which enhance the surface area of the polyp. The contractile tentacles contain sensory cells and stinging capsules. The mouth extends into a gastrovascular or gastric cavity through a short tubular pharynx, which has a modified sidewall that is called the siphonoglyph or sulcus. This serves to drive water into the gastric cavity and from there to the rest of the colony through the canal system. The gastrovascular cavity has eight protruding radially arranged tissue plates (the mesenteries), which have an important function in the polyp hydraulic system, contain digestive gland cells and in most genera, produce the gonads. The lower part of the polyp is embedded in common tissue, the coenenchyme. The coenenchyme is penetrated by a complex system of tubes (solenia) that enable communication among all polyps in a colony (Bayer, 1973; Fabricius and Alderslade, 2001; Samimi-Nami and Ofwegen, 2012).

Octocorals are suspension feeders and their access to food depends on environmental conditions, relying on water currents (Gili and Coma, 1998). Octocoral polyps can filter small organic particles ($< 20 \mu\text{m}$) from the water column, or capture larger particles, intercepting, for example, zooplankton and larvae with their tentacles. The nematocysts (stinging cells) of octocorals are simple, and therefore, their food is limited to small and weakly swimming plankton (Samimi-Nami and Ofwegen, 2012).

Reproduction

Comparable to scleractinians, sexuality in octocorals is highly conserved. Gonochorism, in which mature colonies exhibit male or female reproductive tissues exclusively, predominates in octocorals, with 89% of investigated species exhibiting this form of sexuality (Kahng et al., 2011). In contrast to scleractinians, hermaphroditism, in which both male (spermaries) and female (oocytes) gonads co-occur in the same colony, is relatively rare among octocorals. Octocoral species can also be mixed or parthenogenetic; mixed species have a regular incidence of gonochoric and hermaphroditic colonies and in parthenogenetic species, oocytes produced by female colonies develop into viable planula larvae without fertilization (Kahng et al., 2011).

Similar to many other species of Anthozoa, octocorals are able to reproduce both sexually and asexually. Colony growth of octocorals is a mode of asexual reproduction via budding of polyps. In addition, octocorals exhibit various mechanisms of vegetative propagation (e.g., fission, fragmentation, polyp detachment, branching growth, and stolonal growth), and for some species this asexual proliferation can support high population growth rates (Lasker, 1988; Kahng et al., 2011). These forms of asexual reproduction occur frequently in many shallow-water octocoral species, however, they have yet to be observed among deep-sea octocorals, as knowledge about reproductive processes in deep-sea octocorals is scarce in general (Watling et al., 2011).

There are two basic types of sexual reproduction in octocorals; broadcast spawning and brooding. In broadcast spawning, colonies release gametes into the water column, and fertilization and planktonic development take place in the water column. Two pathways can occur in brooding, either (1) fertilization of eggs occurring in the maternal colony and embryos developing internally in autozooids, siphonozooids or specialized brood chambers (internal brooding) (Kahng et al., 2011; Watling et al., 2011), or (2) eggs or zygotes are released by the polyps but attach on the adult colony surface where they then further develop prior to release (external surface brooding) (Benayahu and Loya, 1983; Kahng et al., 2011; Watling et al., 2011).

In general, studies on shallow-water octocoral species demonstrate that the frequency of broadcast spawning versus brooding varies within Octocorallia by taxonomic order (Watling et al., 2011). Sea pens reproduce exclusively by means of broadcast spawning, whereas shallow water soft coral and gorgonian species appear to be more flexible concerning reproductive strategies, exhibiting broadcast spawning and brooding (Watling et al., 2011), sometimes even within the same genus, as seen in *Alcyonium* (McFadden et al., 2001).

Octocoral Identification

Unlike reef-building stony corals (Scleractinia), the large majority of octocorals do not produce a massive skeleton (but see Fig. 2A), and instead most species produce calcium carbonate skeletal structures consisting of numerous separated microscopic components called sclerites (Fig. 2B). Sclerites provide support and defense from predators and demonstrate a high variability in shape, coloration, surface morphology, and size. These small skeletal elements are formed by poly-crystalline calcite aggregates (a type of calcium carbonate, CaCO_3) deposited on a fine horny fibrous matrix constructed of proteins. Many taxa have an axial skeleton that consists of a dense brown calcified, horn-like substance, gorgonin (a form of collagen) (Jeyasuria and Lewis, 1987), or of sclerites that are densely packed together. This axial structure is what distinguishes the gorgonians from other octocorals (Samimi-Nami and Ofwegen, 2012), and is the main support structure of the gorgonian polyp colony (Jeyasuria and Lewis, 1987).

Octocoral taxonomy has traditionally been based on the study of the shape of the colonies, and the color, size and form of sclerites (Bertson et al., 2001). The relative proportions of the different sclerite types are used as an identification method and have constituted the main criteria for the delimitation of species (Aharonovich and Benayahu, 2012).

The important role of sclerites in octocoral taxonomy was not recognized until the late 1800s and early 1900s, as microscopes were much less advanced at the time. Subsequently, early species descriptions did not include sclerite illustrations, or included only minimal details, hampering the present-day taxonomy and systematics of Octocorallia, as many of these earlier species descriptions often fit multiple species within a specific genus or family.

Fig. 2 Scanning electron microscope images of (A) *Nanipora kamurai* aragonite skeleton from Dongsha Atoll (Taiwan), scale bar 0.5 mm. Photograph: YW Lau. (B) Some sclerite types seen in plexaurid species, from left to right: foliate spheroid (top left), butterfly (bottom left), rod, scaphoid, unilaterally foliate club (sclerites not to scale). Photographs: FR Stokvis.

However, recent papers have shown that octocoral species without sclerites are not rarities, and to date, the absence of sclerites or other calciferous skeletal parts have been found within seven octocoral families: Acanthoaxiidae, Acrossotidae, Cornulariidae, Dendrobrachiidae, Alcyoniidae, Clavulariidae, and Xenidiidae (Alderslade and McFadden, 2007, 2011; López-González et al., 1995; Benayahu et al., 2017a; Lau and Reimer, 2019). The lack of sclerites has important implications for future studies, as they currently represent one of the major diagnostic features of the group (Alderslade and McFadden, 2011; Benayahu et al., 2017a; Lau and Reimer, 2019). Despite a long history of research, it is clear more work on morphological diagnostic features is needed.

Molecular Markers and Phylogenetic Analyses

The classification of many morphologically difficult to identify octocoral groups requires detailed species descriptions and identification keys. However, identification of octocorals at fine taxonomic levels (e.g., genus, species) is usually hampered by the lack of diagnostic characters (Bayer, 1961; Sánchez, 2007). Since 1855, when Valenciennes first investigated octocoral sclerites, the comparative assessment of sclerite diversity has represented the preferred strategy among octocoral taxonomists. However, in recent years, the use of DNA sequences and phylogenetic analyses has become an alternative and important method for the identification and systematics of these organisms.

The monophyly of Octocorallia and its sister relationship to Hexacorallia was confirmed by early molecular phylogenetic studies, which used partial or complete 18S ribosomal DNA sequences (Bridge et al., 1995; Song and Won, 1997; Berntson et al., 1999; Kim et al., 1999; Won et al., 2001; McFadden et al., 2010), partial (Chen et al., 1995) or complete 28S rDNA sequences (McFadden et al., 2010), and partial mitochondrial 16S rDNA sequences (France et al., 1996; McFadden et al., 2010). A short fragment of the mitochondrial gene cytochrome *c* oxidase subunit 1 (Cox1) has been proposed as standard molecular marker for metazoans (Hebert et al., 2003). Although this marker is still widely considered for molecular analyses, its use has shown limitations for anthozoans in general (Shearer et al., 2002; Huang et al., 2008) and specifically for octocorals (McFadden et al., 2011), making Cox1 generally unsuitable as a species-specific marker. On the other hand, the octocoral specific mitochondrial MutS-like protein (mtMutS) has been extensively used for molecular and phylogenetic analyses, providing significant insights into the systematics of the subclass; the unique protein-coding gene provides a synapomorphy for the Octocorallia (McFadden et al., 2010), as it has not been found in the mitochondrial genomes of other metazoans (Culligan et al., 2000; McFadden et al., 2010). Besides mitochondrial DNA, Chen et al. (2009) showed that the nuclear genome of some anthozoans may evolve up to five times faster than the mitochondrial genome, suggesting therefore the need of exploring the nuclear and mitochondrial DNA regions. Nuclear markers such as ATP Synthetase Subunit α (ATPS α), Internal Transcribed Spacers (ITSs) and 28S ribosomal DNA (28S rDNA) have been recently considered for biodiversity assessments and taxonomic surveys of different octocoral taxa (Haverkort-Yeh et al., 2013; McFadden et al., 2014).

The phylogenetic trees published so far, which are mainly based on a handful of mitochondrial and nuclear loci, have shown some topological incongruences. For instance, Berntson et al. (2001), using 18S rRNA, recovered Pennatulacea as polyphyletic, whereas McFadden et al. (2006), with two mitochondrial protein-coding genes (Nad2 and mtMutS), found Pennatulacea monophyletic and placed within alcyonaceans. In the same study, the authors recovered most of the alcyonacean subordinal groups as polyphyletic. Recently, studies on South African stoloniferans (McFadden and van Ofwegen, 2012), deep-sea calcaxonians (Pante et al., 2012) and shallow water scleraxonians (Cairns and Wirshing, 2015; Conti-Jerpe and Freshwater, 2017) have corroborated McFadden et al.'s results, and it is clear that many octocoral groups need taxonomic revisions based on molecular results.

Besides the standard molecular markers, recently, the sequencing of complete mitochondrial genomes has allowed exploration of gene arrangements and/or gene novelty (Brockman and McFadden, 2012; Hogan et al., 2019), testing the use of indel-rich regions

and variable traits as alternative DNA barcodes (Poliseno et al., 2017a), and inferring robust phylogenies using extended coding-protein gene datasets.

Although molecular analyses are now considered standard procedures in taxonomy, technologies such as Sanger sequencing are being quickly replaced by high-throughput sequencing applications, which allow generation of much larger datasets in a short time and with reduced costs. Next generation sequencing applications in octocoral taxonomy include the use of RAD-Seq for species delimitation (Pante et al., 2015; Herrera and Shank, 2016), the recovery of mitogenomes for evolutionary studies (Figueroa and Baco, 2015; Poliseno et al., 2016, 2017b), and, as recently tested by Quattrini et al. (2018), the use of hundreds of ultra-conserved elements and exon loci for deep phylogenomic analyses.

Future octocoral taxonomy will undoubtedly build upon a combination of molecular and more traditional morphological techniques (Conti-Jerpe and Freshwater, 2017). However, the lack of important morphological features, such as sclerites, hold implications for future studies, and thus emphasizes the need for new molecular techniques. For octocorals in particular, the development of reliable species-specific molecular markers is needed. Additionally, the use of extended datasets including mitochondrial and nuclear traits as well as hyper-variable regions could provide better resolution, allowing more reliance on molecular data when morphological information is scarce.

Marine Biogeography, Ecology and Symbioses

Octocorals have been recorded across a wide range of depths, from littoral waters down to deep-sea abyssal depths (deepest octocoral reported *Thouarella vitjaz* Zapata-Guardiola & López-González, 2012 at 6400 m), as well as from the tropics to the arctic regions and from all oceans worldwide (Van de Water et al., 2018). The highest diversity of octocorals has been observed in the shallow coral reefs of the Indo-Pacific (Pérez et al., 2016; Van de Water et al., 2018). In the deep sea, pennatulaceans and gorgonians are the predominant octocoral groups and their biogeography has been recently reviewed by Watling et al. (2011).

Octocorals are such a large and diverse group that marine biogeographical studies have often focused on either specific taxa or regions. For instance, Williams (1992) investigated the octocorallian fauna of South Africa, reporting on the diversity, bathymetric and geographic distribution and abundance of different groups (i.e., soft corals, gorgonians and sea pens) in the Atlantic and Indo-Pacific waters. Vargas et al. (2008) analyzed the distribution patterns of a widespread and species-rich eastern Pacific octocoral genus (*Pacifigorgia*) and reconstructed the geographical distribution, using the data available from museum collections, of most of the species until then described. Recently, the use of DNA sequences allowed reconstruction of the historical biogeography of the genus *Paramuricea* in eastern Atlantic and Mediterranean (Poliseno et al., 2017a), and to estimate the geographical ranges and regional endemism of Indo-Pacific members of the family Xenidiidae (McFadden et al., 2019). Octocoral distribution is often influenced by various environmental parameters (Yesson et al., 2012). However, the conspicuous presence of octocorals in nearly all benthic marine habitats is an indication of the adaptive nature of this taxonomic group (Van de Water et al., 2018). Octocorals play a crucial role in shallow water coral reef communities, as many sessile marine organisms contribute to the high marine biodiversity by acting as host for associated organisms (Hoeksema, 2017; Reijnen et al., 2011). Octocoral communities create three-dimensional networks, providing critical habitat and shelter for associated organisms and other reef dwellers (Wirshing et al., 2005; Sánchez et al., 2003; McFadden et al., 2006; Reijnen et al., 2010), fostering total reef biodiversity. Sea pens, in particular, provide habitat in sandy and muddy locations from shallow to deep waters. Soft corals, gorgonians (including sea fans) act as hosts for organisms such as fish, molluscs and crustaceans. These organisms can use their hosts, for example, as food sources or simply as shelter against predators. An example is the slender filefish, *Monacanthus tockeri*, which can be seen in between the branches of octocorals in the Caribbean, using them as background camouflage for protection (Ben-David and Kritzer, 2005; Sánchez, 2017) (Fig. 3A and B). Octocorals have potentially vulnerable soft tissue yet they appear to be largely free from predation (Pawlik and Fenical, 1992). Sclerites in the soft tissue seem to be the main contributor to defense. In addition to skeletal support, sclerites fulfill a second role as structural defense against predators (West, 1997). However, the bearded fireworm, *Hermodice carunculata*, is an exception and also feeds on soft corals (as well as hard corals, zoantharians, anemones and hydrocorals) by engulfing entire polyps or on entire branch endings by removing the soft tissue (Lewis and Crooks, 1996; Souza et al., 2007). Additionally, gastropods such as ovulid snails (Pawlik and Fenical, 1992) and coralliophilid snails (Meulens, 2012; Del Monaco et al., 2010) can cause tissue damage (West, 1997); rather than killing their host, small quantities of tissue are removed. Colonial invertebrates are only rarely killed by their predators and, due to their modular body plan and capacity for regeneration, they may be little impaired by attacking predators. It should be noted that the wounds resulting from consistent tissue removal, which bares the underlying axial skeleton, can be colonized by algae, causing inhibition of tissue regeneration (Harvell and Suchanek, 1987).

Epibiont appearance and life history are often very well adapted to their specific octocoral host and allow them to live in symbiosis (Reijnen et al., 2011, 2014). Relationships are often so complex that octocorals and their symbionts can act as model organisms to study the evolution of defense strategies (Reijnen et al., 2010, 2011, 2014). Some host-symbiont relationships can be very intricate and one such example are diminutive seahorses (*Hippocampus* spp.), collectively called pygmy seahorses (Lourie and Kuitert, 2008; Reijnen et al., 2011). Some species of the miniature tropical fish, *Syngnathi*, can live in very close association with specific octocorals, mainly sea fans (e.g., *Muricella*, *Annella*, *Acanthogorgia* spp.). For instance, pygmy seahorse species have adapted their coloration and body ornamentation in the form of tubercles to exactly match the shape of the polyps of their gorgonian hosts (Lourie and Randall, 2003) (Fig. 3C and D). The small sizes of pygmy seahorses (the smallest species is around 13.3 mm in length,

Fig. 3 In situ photographs of (A and B) the slender filefish *Monacanthus tuckeri* seeking shelter in the branches of *Plexaurella* sp. Photographs: YW Lau. (C) The pygmy seahorse *Hippocampus barganti* on *Muricella* sp. Photograph: FR Stokvis. (D) *Hippocampus* sp. on *Anella* sp. Photograph: FR Stokvis. (E) The ovulid snail *Pseudosimnia culmen* on *Dendronephthya* sp. Photograph: BT Reijnen. (F) The ovulid snail *Prosomnina draconis* on *Melithaea* sp. Photograph: BT Reijnen.

Hippocampus denise Lourie & Randall, 2003) combined with their excellent camouflage suggests that these animals are easily overlooked and therefore poorly observed, as finding them is usually challenging (Lourie and Randall, 2003; Lourie and Kuitert, 2008).

Little information is available on host specificity and possible intermittent occurrence on octocoral hosts for most pygmy seahorse species (Goh et al., 1999; Reijnen et al., 2011). In addition, host gorgonians are often difficult to identify due to a lack of clear morphological diagnostic characters (e.g., *Annella* spp.). Therefore, to fully understand the intricate relationships between host and symbiont, future studies on pygmy seahorses should also emphasize attention on their octocoral host (Reijnen et al., 2011).

Ovulid snails are another example of obligate associations with cnidarians, with most examples occurring associated with octocorals (Reijnen et al., 2010). Ovulid snails are one of the few parasitic organisms that feed on octocorals and are commonly found on soft corals. Ovulid species have a mantle that covers the shell and are well camouflaged. Like the pygmy seahorse, the mantle of the snails can have bright colors and structures that resemble the branches of their octocoral host (Reijnen et al., 2011) (Fig. 3E and F).

Octocorals do not only host organisms on their surface, but also act as host to organisms that find a home within their tissues. Many octocorals host unicellular algae, dinoflagellates of the family Symbiodiniaceae, which are also called zooxanthellae (Van Oppen et al., 2005). Previous studies investigating the diversity of octocoral-associated zooxanthellae, have found that octocorals harbor five of the seven recently revised genera (*Symbiodinium* Freudenthal, 1962 (formerly "Clade A"), *Breviolum* J.E. Parkinson &

Lajeunesse, 2018 (former “Clade B”), *Cladocopium* Lajeunesse & H.J. Jeong, 2018 (former “Clade C”), *Durusdinium* Lajeunesse, 2018 (former “Clade D”), *Gerakladium* Lajeunesse, 2018 (former “Clade G”) (Franklin et al., 2012; Lajeunesse et al., 2018; Van de Water et al., 2018). The majority of investigated octocorals harbored only a single genus, indicating geographical patterns; *Cladocopium* being dominant in the Pacific Ocean and the Red Sea (Van Oppen et al., 2005; Goulet et al., 2008a,b), *Durusdinium* in Caribbean octocorals (Goulet and Coffroth, 2004; Goulet et al., 2008a,b) and *Symbiodinium* in Mediterranean octocorals (Forcioli et al., 2011). Octocoral-Symbiodiniaceae relationships have received far less attention than those of scleractinian corals and thus there are critical gaps that remain in the understanding of the functional and ecological significance of these symbioses (Van de Water et al., 2018). These obligate mutualistic symbioses play an important role in extending available energy resources and thus potentially influence biodiversity on reefs (Van Oppen et al., 2005; Fabricius and De’ath, 2008).

Economic and Environmental Importance

The majority of taxa from which recent new marine natural products (MNPs) have been reported since 1990 belong to the phyla Porifera (49%) and Cnidaria (28.6%) (Leal et al., 2012). Approximately 99% of the new marine natural products from Cnidaria come from anthozoan species. One of the main sources of these new marine natural products in Anthozoa are octocorals (Leal et al., 2012). Approximately 60% of their extracts are bioactive molecules with medicinal potential (Coll, 1992; Khalesi, 2008), and octocorals can therefore be considered as a promising group for pharmacological uses. Many octocoral species have biologically active metabolites; they can have antibacterial, anticoagulant, antifungal, anti-inflammatory, antimalarial, antiprotozoal, antituberculosis and antiviral properties (Mayer et al., 2010, 2011). These metabolites can be precursors for potential medicines, which has been proven for prostaglandins (Gerhart, 1986; Sammarco and Coll, 1992; Stanley-Samuelson, 1994; Almeida et al., 2014; Weil et al., 2016).

The soft coral *Sinularia flexibilis* (Quoy & Gaimard, 1833) contains highly potent bioactive compounds (secondary metabolites), many of which have important ecological roles in the defense against predation and competition for space (Khalesi, 2008), but have been proposed to be of potential use in the development of antibiotics (Clark, 2000), natural sunscreen and cosmetic products (Volkman, 1999), or even promising anticancer drugs (Weinheimer et al., 1977; Yates and Carlson, 1992). *Antillogorgia elisabethae* (previously assigned to *Pseudopterogorgia*) is one of the few octocoral species that currently has commercial use as it is harvested from the Little Bahama Bank in the Bahamas (Lasker and Porto-Hannes, 2015; Williams and Chen, 2012). Annual harvest data are not publicly available, but the value of the fishery has been estimated to be \$3–4 million (Bruckner, 2002) and the demand for pseudopterogins is estimated at 30–45 t per year (Puyana et al., 2004). Sometimes, the economic benefits from such developments are more productive than local fishing industries (Fabricius and Alderslade, 2001).

Additionally, some octocorals are commercial resources, with some of these well-known since antiquity. For example, the red skeleton of the precious coral genera *Corallium* and *Paracorallium* are very much sought after and have been extensively used for crafts (Ascione, 1993). The history of the utilization of red coral *Corallium rubrum* goes back as early as 30,000 years ago, in which peoples used the skeleton for jewelry, as currency, and as religious talismans (Tescione, 1973; Tsounis et al., 2007). Commercial harvesting of red corals began in the 19th Century (Tsounis et al., 2007) and has a history of heavy overexploitation, raising concerns about the sustainability of collecting precious corals (Tsounis et al., 2013). The regeneration rate of red coral colonies is slow as they are long-lived and slow-growing apex marine organisms (Bramanti et al., 2014). Therefore, Corallidae species are fragile resources vulnerable to human influences (Tsounis et al., 2010). Now, *C. rubrum* is still threatened and has been assigned an endangered status by IUCN (Garrabou et al., 2015). As well, the trade of *C. elatius*, *C. japonicum*, *C. konojoi*, *C. secundum* are controlled legally by annex III of CITES (Convention of International Trade of Endangered Species), are Helioporidae spp. and Tubiporidae spp. Besides from precious corals, members from families Primnoidae and bamboo corals from the family Isididae are also commonly used in the jewelry industry (Tsounis et al., 2010).

Coral reef related tourism is a fast-growing industry and the beauty of octocorals has become a main attraction in scuba diving, and in particular octocorals can form wide “gardens” and beautiful scenery, attracting divers from all around the world. However, tourism on and close to coral reefs can also have negative impacts and cause both direct and indirect pressures on these same reef communities and threaten reef communities (Coma et al., 2004): e.g., degradation and lots of marine life (Hasler and Ott, 2008; Albuquerque et al., 2014; Lamb et al., 2014; Spalding et al., 2017), as well as indirect risks due to poorly planned coastal development, including dredging, building on intertidal spaces, and increases in pollution and solid waste (Davenport and Davenport, 2006; Wongthong and Harvey, 2014; Liu et al., 2012; Spalding et al., 2017). However, the risks from coral reef related tourism are thought to be less than those of fishing, land-based run-off, or coral bleaching (Harriott, 2004; Spalding et al., 2017). In some cases, tourism may even be helpful in reducing certain threats, by offering financial or social incentives for sustainable management (Cater and Cater, 2007; Cruz-Trinidad et al., 2009; Arizpe and Covarrubias, 2010; Spalding et al., 2017), raising environmental awareness (Ong and Musa, 2012), as well as encouragement of coral reef restoration (Dearden et al., 2007).

Octocoral Disease

Under rapid climate change and increasing human pressure, coral reefs are facing dramatic increases in coral-bleaching and disease occurrence leading to unprecedented mortality events (Precht et al., 2016) across a large spectrum of reef organisms (Harvell et al.,

1999), including octocorals. Among the cnidarians, scleractinians and octocorals appear to be among the most disease-impacted groups (Weil and Rogers, 2011).

The first case of an octocoral disease was documented by Morse et al. (1977) in Bonaire and Trinidad in the Caribbean. Populations of the sea fan *Gorgonia ventalina* showed tumor-like growths leading to tissue death and erosion of the affected colony. An alga was identified as the causative agent and it was mentioned that all the observations of tumors occurred on impacted reefs exposed to environmental stress (Morse et al., 1977). However, recently, these purple spots have been shown to be caused by parasitic copepods (Ivanenko et al., 2017). Subsequently, in 1982, the first mass-mortality event involving a Caribbean octocoral, *Gorgonia flabellum*, was reported along the coast of Costa Rica (Guzman and Cortes, 1984); this was the first epizootic in a long series of disease outbreaks. In the 1990s, reports of new coral diseases and devastating disease outbreaks proliferated in the literature. In the Caribbean, thousands of sea fan coral colonies died from the fungal disease *Aspergilliosis* (Smith et al., 1996). Later, in the late 1990s, disease outbreaks affected octocorals in the Great Barrier Reef (Willis et al., 2004). Temperate populations have not been spared and disease outbreaks have been documented in the Mediterranean Sea (Cerrano et al., 2000) and in the cold waters of the English Channel (Hall-Spencer et al., 2007). The last two decades have seen the Eastern Pacific (Sánchez et al., 2014) and the subtropical Atlantic Ocean (Cassola et al., 2016) added to the long list of geographical areas where octocoral diseases seem to thrive.

The latest review on octocorals diseases reports at least 19 known diseases affecting around 42 species worldwide (Weil et al., 2016). In Weil et al.'s (2016) review, disease was defined as any impairment of the normal structure or function of an organism and includes responses to biotic agents such as viruses, fungi or bacteria or environmental factors (Work and Aeby, 2006; Weil et al., 2016).

Investigating marine diseases is not an easy task. Knowledge of marine bacteria is very limited and marine bacteria are very difficult if not impossible to culture in the laboratory (Joint et al., 2010). As a consequence, to date causative agents have been identified for only eight octocoral diseases and these include bacteria, cyanobacteria, virus, fungi, filamentous algae, and parasitic copepods (Weil et al., 2016). The terrestrial fungus *Aspergillus* spp. and the bacterium *Vibrio* spp. are infamous for the death of millions of octocoral colonies in the Caribbean (Smith et al., 1996; Geiser et al., 1998) and the Mediterranean Sea (Bally and Garrabou, 2007), respectively. One major driver common to all diseases affecting octocorals appears to be high seawater temperatures (Van de Water et al., 2018), which have been positively associated with all major massive mortality events. However, whether high temperatures increase pathogen virulence or decreases host resistance, or a combination of both, remains to be determined.

Bleaching, i.e., the loss of coloration due to the loss of endosymbiotic Symbiodiniaceae in response to elevated temperature, falls within the definition of disease (Weil et al., 2016). Mass bleaching and mortality events have been reported worldwide in octocoral communities, and as with zooxanthellate scleractinian corals are due mostly to sustained periods of extreme heat, in the Caribbean and the Pacific during El Niño events in 1998, 2005, and 2010 (Loya et al., 2001; Strychar et al., 2005; Goulet et al., 2008a,b; Slattery et al., 2019), and in the Mediterranean Sea during the 2003 heat wave (Garrabou et al., 2009). In addition, bleaching is known to impair anthozoan physiology and thus increase vulnerability to microbial diseases (McClanahan et al., 2009).

Compared to scleractinians, octocorals appear to have higher resistance to bleaching due to their lower dependency on dinoflagellate symbionts (Fabricius and Klumpp, 1995). However, a recent study by Baker et al. (2015) demonstrated that not all octocoral species can afford to lose their symbionts. There have already been cases in which reef ecosystems have undergone a so-called phase shift from a hard coral-dominated state toward a higher abundance of soft corals (Van de Water et al., 2018). However, additional studies are necessary to investigate the energetic needs of octocorals and their resilience and recovery subsequent to bleaching events (Van de Water et al., 2018).

Mass bleaching and mortality events have been reported worldwide in octocoral communities, and as with zooxanthellate scleractinian corals are due mostly to sustained periods of extreme heat, in the Caribbean and the Pacific during El Niño events in 1998, 2005 and 2010 (Loya et al., 2001; Strychar et al., 2005; Goulet et al., 2008a,b; Slattery et al., 2019), and in the Mediterranean Sea during the 2003 heat wave (Garrabou et al., 2009). In addition, bleaching is known to impair anthozoan physiology and thus increase vulnerability to microbial diseases (McClanahan et al., 2009).

Among all octocorals, gorgonians are clearly the most affected by abnormal health conditions, but they have also been observed on soft corals. There have been no records of diseases affecting Pennatulacea, *Heliopora* or the suborder Stolonifera thus far. In the Caribbean, the relative abundance of octocorals has increased over the years as a consequence of the decline of scleractinian species (Edmunds and Lasker, 2016), and in several places, a gradual transition from scleractinian to soft corals has occurred (Lenz et al., 2015). Therefore, in the context of climate change, the increasing susceptibility to disease of octocoral populations may have important consequences in terms of community composition structure and function, and in terms of biodiversity, and therefore also with regards to economic and ecological services. Despite the mass mortality events recorded in the past, the consequences of such losses are still poorly understood. However, recent studies conducted in the Mediterranean Sea have demonstrated that gorgonians can influence the composition and abundance of vagile assemblages (Ponti et al., 2016). In Okinawa, Loya et al. (2001) reported drastic changes in soft coral community structures following coral bleaching, including a notable decrease in soft coral cover as well as a shift in species dominance due to differential susceptibilities of bleaching. In the Mediterranean Sea, the disappearance of gorgonians may also cause a shift from important bio-constructors such as crustose coralline algae to filamentous algae assemblages (Ponti et al., 2014). This would in turn impair the complexity and resilience of these fundamental bio-constructions and their ecosystems (Ponti et al., 2014).

Conclusions and Future Directions

Although octocorals are affected by pollution, diseases and global climate change (Van de Water et al., 2018) and their ecological importance and role in coral reef communities is increasingly being emphasized (Ruzicka et al., 2013; Tsounis and Edmunds, 2017), the research attention they have received is still significantly less when compared to that of scleractinian corals (Prada et al., 2010; Van de Water et al., 2018).

A better knowledge of octocorals becomes especially relevant in light of the phase-shifts that coral communities are facing under increased climate change and global warming and other anthropogenic influences. Basic knowledge about octocoral taxonomy and their systematics have yet to be unraveled, and the development of novel methods to achieve this goal are yet to be accomplished. Taxonomic documentation is key to communicating biological information and establishing biodiversity. Combining it with ecology and knowledge on the functional roles of octocorals on coral reefs could contribute in the development of strategies in building resilience in coral reef communities (Van de Water et al., 2018).

Acknowledgments

We would like to thank Frank R. Stokvis (Naturalis Biodiversity Center) for providing scanning electron microscope (SEM) images of sclerites of plexaurids and in situ photographs of pygmy sea horses on octocorals. We thank Dr. Bastian T. Reijnen for permission to use in situ photographs of ovulid snails on octocorals.

Abstract

DNA metabarcoding is now a well-established method that uses DNA sequencing techniques and bioinformatics to identify a wide variety of species from mixed samples, such as gut content and sea water samples. A major benefit of this method is its sensitivity, which allows the detection of the presence of animals in the sampled environment, without having to collect or kill specimens. It is thus a great biomonitoring tool to assist in marine conservation and management. This article provides a brief overview of DNA metabarcoding touching on the essential elements that should be considered when using this method (e.g., marker regions and DNA database coverage) and how it is being incorporated into marine research (e.g., detecting invasive species).

What Is DNA Metabarcoding?

DNA metabarcoding uses high-throughput DNA sequencing (HTS) for the taxonomic identification of multiple species from a mixed sample. It is an extension of the highly popular “DNA barcoding” approach, which has been used very successfully to identify individual specimens to species level ([Kress and Erickson, 2008, 2012](#); [Kress et al., 2015](#)). DNA metabarcoding can have considerable advantages over traditional morphological identification, as it can be more rapid, accurate, sensitive, and cost-effective. The types of mixed samples that can be analyzed using this method include seawater, fecal matter, mucus, sediment, and gut content. DNA metabarcoding thus allows for detection of a species without directly sampling it. Mixed samples are dealt with in two ways: either in a targeted approach whereby organisms, or tissues, of interest, are isolated from the mixed sample prior to DNA extraction; or in a nontargeted approach whereby all DNA is extracted from the entire mixed sample ([Fig. 1](#); [Deiner et al., 2017](#); [Nielsen et al., 2018](#); [Taberlet et al., 2018](#)).

The laboratory analysis portion (e.g., sample dissection, DNA extraction and DNA amplification) of DNA metabarcoding can have a great influence on the end results, and each step (starting from sample collection and preservation) that leads to the final identifications should be considered critical and be undertaken in a uniform manner. DNA extraction is the first molecular step in the DNA metabarcoding process and, although not essential, specialized DNA extraction kits can be very beneficial, as they have been developed to suit different source material (e.g., seawater or fecal matter; [Hermans et al., 2018](#); [Jeunen et al., 2019](#)). DNA degradation is highly likely in environmental samples and thus extracting high molecular weight DNA from these samples is generally unlikely. This means that targeting a 300 base pair (bp) portion of a marker (barcode) region is likely to be more successful than targeting a 1000 bp portion of the same marker region. Thus, choices of marker regions and primers are critical ([Alberdi et al., 2018](#)). Marker regions selected for DNA barcoding are generally housekeeping genes, such as mitochondrial DNA cytochrome oxidase I (COI) or 16S/18S ribosomal RNA (rRNA) genes. These gene regions have been largely conserved in many species over time, but also have intervening regions where the DNA sequences have diversified sufficiently to enable discrimination among closely related species. Thus, these regions can be seen as a unique code for identifying species and are known as DNA barcodes. These regions are targeted during DNA amplification in a process known as polymerase chain reaction (PCR) and when mixed samples are used, such as in DNA metabarcoding, a pair of universal primers needs to be used in order to amplify the targeted gene region from a wide variety of species that may be present in the sample.

Primers are DNA oligonucleotides, which are short nucleic acid sequences that are synthesized in the laboratory. They each anneal to a specific location on the DNA during PCR, and provide a consistent starting point for DNA replication. Universal primers have been designed to amplify the same DNA region from diverse species in a single PCR. Because the most common current methods of HTS (e.g., Illumina MiSeq™ platform) provide shorter DNA sequence reads (currently 2×300 bp length) than traditional Sanger sequencing methods (up to 1000 bp), specialized PCR primers are required for DNA metabarcoding that amplify much shorter DNA fragments than the traditional barcoding genes. Although this brief overview of DNA metabarcoding describes PCR-based methods, it should be noted that PCR-free methods can also be used (e.g., shotgun sequencing

Fig. 1 An illustration of a targeted and nontargeted DNA metabarcoding approach. (A) Targeted DNA metabarcoding (i) is a process whereby organisms of interest (e.g., krill) are first isolated from the mixed samples (e.g., seawater), whereas in nontargeted DNA metabarcoding (ii) there is no selection from the raw samples (e.g., feces). (B) DNA extractions isolate the available DNA in the mixed samples. (C) Polymerase chain reactions (PCRs) amplify only the DNA from the marker region of interest (e.g., COI). (D) High-throughput DNA sequencing (HTS) provides the raw DNA sequences of the PCR products. The raw sequencing data is filtered using a bioinformatics pipeline (e.g., Qiime 2). Only the most reliable sequences are retained and are generally clustered into highly similar groups of sequences (molecular operational taxonomic units; MOTUs or OTUs). Each OTU's consensus sequence is then matched to a reference sequence from a chosen DNA database (e.g., Genbank or Midori), thus assigning taxonomic identities to the OTUs. (E) In a targeted approach it is expected to only identify species relevant to the organisms that were selected (i), but from a nontargeted approach it is expected that a wide variety of organisms may be identified (ii).

and mitochondrial enrichment; Zhou et al., 2013; Tedersoo et al., 2015; Liu et al., 2016; Kimmerling et al., 2018; Mariac et al., 2018; Jo et al., 2019; Stat et al., 2019).

Once DNA amplification has been undertaken for the specific marker region/s of interest, then the PCR products are sequenced on a next-generation sequencing platform (e.g., Illumina MiSeq™). The raw HTS data undergoes analyses where the sequences are filtered for quality, and highly similar filtered sequences are clustered together and consensus sequences are derived. The different consensus sequences are known as molecular operational taxonomic units (MOTUs or OTUs) and are compared to reference DNA databases in order to assign taxonomic identity to the OTUs. The quality filtering and clustering is undertaken using bioinformatic pipelines; open-source pipelines include Qiime 2 (Bolyen et al., 2019), Mothur (Schloss et al., 2009), and Obitoools (Boyer et al., 2016). Amplicon sequence variant (ASV) methods can also be used, instead of using OTU methods, and may be the preferred method in future, but detailed discussion of this topic falls outside the scope of this brief overview (Callahan et al., 2017).

The DNA sequence reference databases may be noncurated, i.e., a public repository with little taxonomic quality control, such as the National Center for Biotechnology Information (NCBI) Genbank database (Benson et al., 2013). Alternatively, it may be curated with only selected sequences that meet various taxonomic quality controls, such as Midori (Machida et al., 2017) which is a COI database, and SILVA (Quast et al., 2013) which is a small and large subunit rRNA database. Marker choice for studies is usually influenced by database coverage of target organisms and the resolution that it may provide (Alberdi et al., 2018; Nielsen et al., 2018). For example, many large metazoans are best discriminated using the mitochondrial DNA COI barcode region, whereas rRNA regions are often best suited to microorganisms (van der Reis et al., 2018).

Generally, multiple DNA extractions, multiple PCRs of those DNA extractions, and multiple DNA markers are all beneficial when wanting to identify the most complete set of taxa possible from a mixed sample. The cost can be minimized for sequencing by pooling (equimolar concentrations) across PCR replicates for a single sample per gene and then pooling again across different genes for a single sample. However, this strategy is dependent on the question of interest, the diversity within the sample, and the time and financial constraints of the study at hand. Overall, DNA metabarcoding is applicable in multiple areas of research involving community ecology and can provide sensitive biodiversity data that was previously inaccessible.

Applications of Marine DNA Metabarcoding

Many of the deepest parts of the oceans are yet to be explored and those areas that have been explored are still poorly understood. This is largely due to the difficulties of observing marine life directly in its natural environment, compared to the more easily observed terrestrial life, thus making the task of understanding marine ecological communities more complex.

Marine biodiversity characterization using DNA metabarcoding, over a period of time, can assist in biomonitoring (Valentini et al., 2016; Stat et al., 2017; Cahill et al., 2018; Cristescu and Hebert, 2018; Siegenthaler et al., 2018; Taberlet et al., 2018). Biomonitoring is mainly used in two types of applications which are very closely linked, the theoretical understanding of ecological processes and the practical application to marine conservation and management. This information can indicate the health of a community and if it may be under threat, such as the absence of species of conservation interest, or the presence of invasive species. There is potential to assess relative abundance of species using DNA metabarcoding, although the way to determine abundance should be approached with caution (Pompanon et al., 2012; Thomas et al., 2016; Taberlet et al., 2018; Deagle et al., 2019; Lamb et al., 2019; Piñol et al., 2019). One of the most beneficial aspects of incorporating the use of DNA metabarcoding as a biomonitoring tool is that more detailed diversity information is gained at each time point, and thus when repeated over time changes can be much more accurately assessed (Jarman et al., 2018). These changes may relate to the progress of restoration of marine areas, monitoring fluctuations in marine protected areas or marine areas that are thought to be affected by human activities, such as oil drilling.

Some examples of the use of DNA metabarcoding in ecological processes would include how ocean warming and climate change may be affecting pelagic food webs. In addition to detecting the presence of species in the environment, DNA metabarcoding can also be used on animal gut contents to provide information on prey composition (Young et al., 2015). It can also be used in understanding what impacts invasive species may have on native species, by identifying and monitoring the invasive species' diet to see how it may impact the native community in future (Harms-Tuohy et al., 2016). The management of fisheries includes both ecological processes and marine conservation and management. The reconstruction of food webs and thus identifying trophic levels and keystone predators (e.g., using DNA metabarcoding on gut content or water samples) is critical for sustainable fisheries management (Riccioni et al., 2018) and pathogenic microorganisms detected may even indicate the health of the community and threats to commercial species. Moreover, DNA metabarcoding could be coupled with more traditional fisheries management (e.g., traditional net surveying) and marine monitoring in general, to assess species distribution (Malviya et al., 2016; Bakker et al., 2017; Cahill et al., 2018; Deiner et al., 2017; Lobo et al., 2017; McInnes et al., 2017; Grey et al., 2018; Siegenthaler et al., 2018). Siegenthaler et al. (2018) demonstrated how DNA metabarcoding can complement traditional net surveys, by using a marine benthic generalist's gut contents to detect twice as many fish species when compared to traditional net surveys. It has also been used to assess the biological impacts that offshore activities, such as gas or oil drilling, may have on the biodiversity in that area and to identify potential taxa that could be utilized for assessing environmental health (bioindicators) (Laroche et al., 2018; Cordier et al., 2019).

Another major application of DNA metabarcoding is in biosecurity for the detection of toxic, pathogenic, and invasive species (Viard and Comtet, 2015; Zaiko et al., 2015, 2018; Xiong et al., 2016). DNA metabarcoding can also be applied to wildlife forensics, and the monitoring of rare, endangered and/or threatened species (Staats et al., 2016; Pikitch, 2018). A major benefit of using DNA metabarcoding for biomonitoring (e.g., biosecurity, rare/invasive species or wildlife forensics) is that it can be extremely sensitive to the presence of low numbers of such organisms or low concentrations of DNA, and can be immediately applied to the detection of a wide range of such species. This is in contrast to more targeted, species-specific monitoring such as DNA probe approaches, which may take a long period to optimize for monitoring.

DNA metabarcoding is also particularly useful in applications such as determining diet, where often no morphological features remain for taxonomic identification. Such dietary information provides insight into the broader biodiversity and food web structure that is present in the predator's surroundings. Through such diet analyses, it has been proposed to use abundant benthic marine generalists as natural biomonitors for ecosystems; individuals can be sampled regularly and thus allow an ecosystem's inhabitants to be identified and monitored (Siegenthaler et al., 2018).

DNA Metabarcoding Limitations

DNA metabarcoding is useful for assessing taxonomic composition of mixed samples within a short time and with little effort per sample. It requires little taxonomic expertise for fast, reliable and accurate taxonomic assignment, and even fully digested material can be used. However, the accuracy of this type of taxonomic identification is largely dependent on the reference databases available. At present, these are still incomplete, but the DNA metabarcoding approach has the benefit that identifications may be improved to a finer taxonomic resolution with time, as the sequence data can be reanalyzed with ease when the databases are updated (Leray et al., 2013; Aylagas et al., 2018; Devloo-Delva et al., 2018; Nielsen et al., 2018). There are currently substantial efforts being made to sequence reference organisms from species in a wide range of taxa and thus it is expected that the databases will improve dramatically in a short time-frame. Marker region and primer selection also play a role in the efficiency and accuracy of taxon detection, as this will determine how fine the taxonomic resolution is and ultimately what database would be best suited for the selected marker region and targeted organisms.

Ultimately, taxonomic expertise will still be needed to compile accurate and complete sets of reference specimens for DNA sequencing. However, traditional taxonomic methods have been shown to be poorer in detecting and identifying taxa in mixed samples than modern DNA metabarcoding methods (Jakubavičiūtė et al., 2017; Granquist et al., 2018; Siegenthaler et al., 2018). Some studies still benefit from coupling traditional taxonomic assignment methods with modern taxonomic assignment; generally this is best for quantitative analyses. However, a major goal of many DNA metabarcoding studies has been to not only identify the range of species present, but also estimate their relative abundance in the sample. As the range of potential quantitative biases became better understood, the consensus opinion became that DNA metabarcoding should be used cautiously for quantitative analyses (e.g., Lamb et al., 2019). Recent advances provide some hope in this endeavor, particularly in well-understood systems, and where quantitative controls can be used (e.g., Thomas et al., 2016). Alternatively, PCR-free approaches may offer the most promising way forward (e.g., Mariac et al., 2018).

Small differences among species in DNA sequence at the primer annealing sites can result in differences in the rate of PCR amplification. This “amplification bias” among species means that the number of DNA fragments sequenced from each species is not likely to accurately reflect the true relative abundance of individuals of those species in the original sample. Such “quantitative” DNA metabarcoding is feasible, but requires strict comparative controls (Alberdi et al., 2018). At the extreme, amplification bias can result in some divergent taxonomic groups being very poorly amplified by a specific PCR primer set, and thus not detected at all in the final analysis. It is not yet possible to design a single primer set that is truly universal, and this is why the use of either multiple primers for the same gene region and/or different marker regions is encouraged, in order to minimize amplification bias and increase the taxonomic diversity detected (Deagle et al., 2013; Clare, 2014; Leal and Ferrier-Pagès, 2016; Alberdi et al., 2018; van der Reis et al., 2018; Corse et al., 2019). This is especially critical when target communities are highly diverse or even unknown (e.g., in the case of gut contents). Having multiple primers for a single marker region and the use of multiple gene regions increases the possibility of detecting different taxa, and provides a more comprehensive picture of the community.

PCR inhibition, another potential PCR amplification bias, is common when trying to amplify the DNA extracted from many environmental samples containing inhibitory compounds, resulting in a lowering of biodiversity detection. To combat this, systematic PCR optimization (including trialing different PCR reagents and the use of quantitative PCR on serially-diluted DNA templates) can be extremely useful (van der Reis et al., 2018). The DNA used in a PCR should be in a homogenous state before PCR amplification. However, this does not ensure that DNA from all taxa is present, due to the small volume of DNA used in a single PCR, and the varied concentrations of extracted DNA from different taxa (causing PCR amplification stochasticity). Thus, replicate PCRs for the same sample should be undertaken in order to increase the chances of amplifying DNA from majority, if not all, taxa that are present in the mixed sample. This increases the chances for detection of rare species and reducing false negatives. PCR replicates are generally pooled together by sample before sequencing in order to minimize costs. These methods will allow the maximum proportion of the true diversity to be detected (O’Rourke et al., 2012; Schrader et al., 2012; Leray and Knowlton, 2015; Murray et al., 2015; Laroche et al., 2017; Alberdi et al., 2018, 2019). While DNA metabarcoding has been found to detect more of the taxa present than when using traditional methods, it is always advisable to undertake a preliminary study to identify potential weaknesses. For example, assessing which primer sets are beneficial to the study—how complete and reliable is their taxonomic resolution?

Finally, the great sensitivity of PCR is one of the strengths of DNA metabarcoding, but it can also be a problem, in terms of false positives. These can arise from sources such as traces of contaminating DNA (including human) during sampling, transport, storage, and laboratory analysis. Thus, great care needs to be taken in the interpretation of OTUs represented by a small number of sequences. These can be controlled to some degree by (i) employing minimum limits on the number of sequence copies required for the inclusion of an OTU in the final list of confirmed species present in each sample, (ii) investigating which species are present in the controls and/or (iii) relying on consistent presence of a species in all PCR sample replicates. However, this will not remove all false positives or artefactual sequences and likely could remove false negatives or true sequences that originated from low DNA concentrations. Therefore, one can take many different DNA sequence filtering approaches in order to provide more confidence in identifications. These include being more stringent in regards to OTU clustering and applying a minimum sequence copy number needed for each OTU to be retained. However, if this approach is too conservative the chance is high that rare taxa are removed from the dataset (potential loss in biodiversity due to the removal of false negatives). However, the taxa that remain have a higher probability of accurately representing the mixed sample, e.g., through removal of secondary PCR products such as chimeric sequences—false positives (Burgar et al., 2014; Clare et al., 2016).

Conclusion

There are many benefits that DNA metabarcoding brings to ecological studies, such as noninvasive environmental sampling and the detection of a species recent presence, and these have accelerated progress in our understanding of marine ecological processes. It has the potential to be incorporated with traditional marine biomonitoring, assisting with species identification of entire communities. The sensitivity of DNA metabarcoding requires that great care be taken during sampling and laboratory work to avoid sample contamination, as well as during computer analyses to have an accurate interpretation of the data. However, it is clear that this technique is now a powerful tool for marine ecological understanding and management.

Further Reading

We have used the most recent DNA metabarcoding articles as references. We encourage anybody new to the topic to start with the very helpful book, “Environmental DNA: For biodiversity research and monitoring,” by [Taberlet et al. \(2018\)](#). Included in the reference list are many insightful DNA metabarcoding review articles that go into depth about topics we have touched on, such as [Deagle et al. \(2019\)](#) “Counting with DNA in metabarcoding studies: How should we convert sequence reads to dietary data?” and [Alberdi et al. \(2018\)](#) “Scrutinizing key steps for reliable metabarcoding of environmental samples.”

Abstract

Zoantharians (Cnidaria: Hexacorallia: Zoantharia) are sessile animals found from the intertidal zone to the abyssal ocean in a variety of marine ecosystems such as coral reefs and sandy seafloors. Although some Zoantharia species produce toxic secondary metabolites, their colonies serve as food sources and shelter to many organisms. The metabolites produced by zoantharians have shown promising results in the pharmacognosy industry. Additionally, some species are popular in the aquarium hobby or as jewelry. The order Zoantharia, with 9 families and 28 genera, has representatives occurring worldwide. Zoantharia are thought to have unique distribution patterns for marine anthozoans. For example, the group appears to have relatively low rates of endemism, with some species having very wide distributions inside each ocean basin. As well, there are several pairs of sibling species between the Atlantic and Indo-Pacific oceans. Due to the importance of the order Zoantharia, additional research in the systematics and distribution of species will help achieve a better understanding of evolution in marine ecosystems. In this article we provide an overview of the group and comment on possible future research trends.

Introduction

Morphology

Zoantharians (Anthozoa: Hexacorallia) are an order of benthic cnidarians with polyps that have a central mouth in the oral disk with one ciliated groove, which creates water currents towards the gastric cavity (Haddon and Shackleton, 1891, Fig. 1). The main external morphological characters used for identification are the color, shape, and size of the polyps and the number of tentacles, which are always in two rows around the oral disk. Additionally, characters of the internal anatomy including the types and number of mesenteries, arrangement of the marginal musculature, and the types and sizes of stinging cells (=cnidae) are also useful in identifying species (Carlgren, 1900; Pax, 1910; Lwowsky, 1913; Ryland et al., 2000; Low et al., 2016).

Most species are colonial, with individual polyps connected by a common tissue. However, species in the genera *Abyssoanthus* and *Sphenopus*, for example, have solitary polyps (Steenstrup, 1856; Reimer et al., 2007a,b). Although zoantharians do not produce a carbonate skeleton, most species are able to aggregate sediment into their tissue, such as sand grains and sponge spicules. This contributes to polyp formation, and some species can have up to 45% of their wet tissue weight being sediment (Haywick and Mueller, 1997). However, representatives of the family Zoanthidae (genera *Acrozoanthus*, *Isaurus*, and *Zoanthus*) and the genus *Kulamanamana* (in family Parazoanthidae) are exceptions with sediment-free polyps (Rafinesque, 1815; Sinniger et al., 2013). Furthermore, some zoantharian genera are able to produce a scleroprotein layer (e.g., *Kulamanamana* and *Savalia*; Ocaña and Brito, 2003; Sinniger et al., 2013).

Systematics

The order Zoantharia is divided into two suborders according to mesentery arrangement; Brachyknemina and Macroknemina (Haddon and Shackleton, 1891). Mesenteries are internal tissues that are sheet-like partitions extending from the polyp wall into the gastrovascular cavity. A mesentery is complete when the tissue connects the polyp wall and the gastrovascular cavity, while an incomplete mesentery does not reach all the way until the cavity. These two suborders are delineated based on the character of the fifth mesentery pair, either being complete (macroknemic, species of the suborder Macroknemina) or incomplete (brachyknemic, species of the suborder Brachyknemina). Although this division is still accepted (Low et al., 2016), molecular studies have shown that Macroknemina is not monophyletic as these species do not share a common recent ancestor (Sinniger et al., 2005; Swain, 2010, 2018). Therefore, the classification at the suborder level of the order Zoantharia requires revision.

Taxonomic research of zoantharians has a history of being neglected, mostly due to species' simple body plans, with relatively few diagnostic characters, and a high rate of intra-specific morphological plasticity (Burnett et al., 1997; Ryland and Lancaster, 2004; Kamezaki et al., 2013). For example, the size and color of polyps of the same species can have a high amount of variation depending on hydrodynamic regime or on the amount of shading or sunlight (Ong et al., 2013).

Molecular studies of the diversity of Zoantharia started with Burnett et al. (1995, 1997) using proteins, and from the early 2000s researchers have used fragments of mitochondrial and nuclear DNA markers (e.g., Reimer et al., 2004, 2006, 2007a,b; Sinniger et al., 2005, 2008; Risi and MacDonald, 2016). These molecular studies have improved our knowledge about the phylogenetic positioning of Zoantharia clades and have also clarified which characters are more useful to delineate species, in addition to leading to more knowledge of the zoantharian diversity of many locations around the globe (Reimer et al., 2008; Koupaei et al., 2014; Santos et al., 2016).

Table 1 Systematics of the order Zoantharia (Low et al., 2016; Horton et al., 2019).

Suborder	Family	Genera
Brachycnemina	Neozoanthidae	<i>Neozoanthus</i>
	Sphenopidae	<i>Palythoa</i> <i>Sphenopus</i>
	Zoanthidae	<i>Acrozoanthus</i> <i>Isaurus</i> <i>Zoanthus</i>
Macrocnemina	Epizoanthidae	<i>Epizoanthus</i> <i>Paleozoanthus</i> <i>Thoracactis</i>
		<i>Aenigmanthus</i> <i>Hydrozoanthus</i> <i>Terrazoanthus</i>
		<i>Antipathozoanthus</i> <i>Bergia</i> <i>Bullagummizoanthus</i> <i>Corallizoanthus</i> <i>Hurlizoanthus</i> <i>Isozoanthus</i> <i>Kauluzoanthus</i> <i>Kulamanamana</i> <i>Mesozoanthus</i> <i>Paleozoanthus</i> <i>Parazoanthus</i> <i>Savalia</i> <i>Umimayanthus</i> <i>Zibrowius</i>
	Hydrozoanthidae	<i>Microzoanthus</i> <i>Nanozoanthus</i> <i>Abyssozoanthus</i>
	Parazoanthidae	
	Microzoanthidae	
	Nanozoanthidae	
	Abyssozoanthidae	
Incertae sedis		

The order Zoantharia currently has 9 valid families and 28 genera (Table 1). However, the total species richness of Zoantharia is not clear due to the recognition of a high number of potential species synonyms (Burnett et al., 1995, 1997; Reimer et al., 2010; Risi and MacDonald, 2016; Santos et al., 2019) combined with large numbers of undescribed specimens at species or higher taxonomic levels (Reimer et al., 2012, 2017a,b; Kise and Reimer, 2016; Santos et al., 2016, 2019).

Ecological Interactions

There are three main types of ecological interactions reported for species of Zoantharia: (1) hosting microalgae (Class Dinoflagellata, Family Symbiodiniaceae) inside their tissues (i.e., endosymbionts); (2) growing attached to another benthic marine invertebrate group; and (3) serving as shelter and prey for other animals.

Symbiotic Algae

Zoantharian and associated endosymbionts are able to exchange nutrients and these microalgae provide carbon-based photosynthates to their host (Muscatine and Hand, 1958). Apart from representatives of the genus *Sphenopus* (Steenstrup, 1856) and three *Palythoa* species (*P. mizigama*, *P. umbrosa*, and *P. macmurrichi*; Haddon and Shackleton, 1891; Irei et al., 2011), all brachycnemic species host these symbionts. Likewise, some macrocnemic species also have obligatory or facultative endosymbiosis. The identity of Symbiodiniaceae genera (Lajeunesse et al., 2018) associated to zoantharians has primarily been investigated using DNA sequences of the molecular nuclear internal transcribed spacer 2 region, and species of Zoantharia are known to be associated with genera *Breviolum*, *Cladocypium*, *Durusdinium*, and *Symbiodinium* (former *Symbiodinium* “clades” B, C, D, and A, respectively; reviewed in Santos, 2019).

Marine Invertebrates as Substrata

Many Zoantharia lineages have symbioses with other benthic invertebrates (Fig. 2), in which the zoantharian polyps grow attached to animals such as Annelida, Arthropoda, Cnidaria, Echinodermata and Porifera. Most macrocnemic lineages have evolved

Fig. 2 Zoantharian symbioses with marine invertebrates. *Acrozoanthus australiae* and *Epizoanthus inazuma* with eunicid worms (A and B, respectively), *Antipathozoanthus remengesau* and *Savalia savaglia* with antipatharians (C and D, respectively), *Corallizoanthus tsukaharai* with octocoral (precious coral) (E), *Epizoanthus* cf. *paguricola* with hermit crab (F), *Hydrozoanthus gracilis* with hydrozoan (G), and *Umimayanthus chanpuru* with sponge (H). Images credits: MEA Santos (A, B, G and H), JD Reimer (C), E Trinito (D), S Nakachi (E), and T Moritaki (F).

facultative or obligatory symbiotic relationships, such as the genera *Bergia* and *Umimayanthus* with sponges (West, 1979; Montenegro et al., 2016) and the genus *Hydrozoanthus* with hydrozoans (Sinniger et al., 2010). Additionally, one brachycnemic genus has obligatory associations with Eunicidae worms and their polyps are only observed growing attached to the worm tubes (genus *Acrozoanthus*, Saville-Kent, 1893; Reimer et al., 2011).

Although Zoantharia-invertebrate interactions have not been comprehensively studied, research has indicated that the associations can range from mutualism to parasitism. For example, the zoantharian *Zibrowius primnoides* kills the tissue of their octocoral host to use their hard axis as attachment substratum (Carreiro-Silva et al., 2011, 2017). On the other hand, some

Zoantharia species do not seem to harm some sponge and worm hosts (West, 1979; Montenegro et al., 2015; Kise and Reimer, 2016). The influence of zoantharians on their sponge hosts in the Caribbean finds both positive and negative interaction outcomes (Lewis, 1982; Lewis and Finelli, 2015; Swain and Wulff, 2007; Swain, 2012). Furthermore, it is possible that zoantharians give advantages to hermit crab partners, as metabolites of their polyps could provide protection against predators. In addition, some of these zoantharians excrete a chitin layer that may enable the crab to grow a large shell (Ates, 2003). Likewise, the hydroid *Plumularia habereri* reaches its largest colony sizes when the zoantharian *Hydrozoanthus gracilis* is associated with it, indicating a possible beneficial interaction (Di Camillo et al., 2010). Nevertheless, the large majority of these potential interaction outcomes have not been tested. Many of these zoantharian symbioses are not limited to shallow waters but also reported from mesophotic reefs and the deep-sea (e.g., Carlgren, 1927; Sinniger et al., 2013; Ryland and Ward, 2016; Carreiro-Silva et al., 2017; Reimer et al., 2019).

Habitat Forming

Zoantharians are used for housing and protection by organisms that live upon, under, or even inside their colonies (Fig. 3). Among associated fauna are small crabs, worms and flatworms, as well as larvae of invertebrates and nudibranch juveniles (Den Hartog and Holthuis, 1984; Den Hartog and Turkay, 1991; Pérez et al., 2005; Trivedi and Vachhrajani, 2014; Biondi et al., 2019; Bee Yan and Ng, 2019). Most of these associations have been observed on the zoantharian genera *Palythoa* and *Zoanthus* (but see *Parazoanthus* reported in Den Hartog and Holthuis, 1984).

Predators

Despite many zoantharian species having sediment in their tissue, as well as stinging cells and toxic metabolites, some animals are able to eat zoantharian polyps. Zoantharia are known to be food sources for echinoderms (Obuchi and Reimer, 2011), fireworms (Ott and Lewis, 1972; Suchanek and Green, 1982; Sebens, 1982; Gleibs and Mebs, 1995; De Assis et al., 2017), fishes (Randall and Hartman, 1968; Sebens, 1982; Bonaldo et al., 2005; Francini-Filho et al., 2010; Longo et al., 2012), nudibranchs (Gosliner, 1985; Bertsch et al., 2009; Kumari et al., 2019), prosobranch gastropods (Robertson, 1967, 1980), and sea turtles (Stampar et al., 2007; Hart et al., 2013; von Brandis et al., 2014; Proietti et al., 2015; Spier and Gerum, 2017). Zoantharia feed on plankton and particles suspended in the water column, and some *Palythoa* species are known to have relatively high plankton feeding rates compared to other anthozoans (Sebens, 1977; Fabricius and Metzner, 2004; de Santana et al., 2015). Thus, such zoantharians are important trophic links, and in addition some zoantharians can also transfer metabolites to higher trophic levels (Gleibs and Mebs, 1999).

Similar to studies of associated fauna, predation records are mainly of the most common zoantharians in shallow-waters, the genera *Palythoa* and *Zoanthus*. For example, adult and juvenile nudibranchs that live on colonies of *P. mutuki* can eat the zoantharian mucus (Kumari et al., 2019). Additionally, field observations have noted the predation of *P. caribaeorum* and *Z. sociatus* by hawksbill turtles in Brazil (Stampar et al., 2007; Proietti et al., 2015), while the gastric content of this turtle species in Caribbean can be up to 86% *Z. sociatus* (Hart et al., 2013). The fact that *Zoanthus* tissues are sediment-free might make them easier to digest compared to *Palythoa* species with high sand content.

Fig. 3 *Palythoa caribaeorum* with a fireworm ("FI" arrow) predator in Brazil (A) and *P. tuberculosa* hosting flatworms ("FA" arrow) inside the tissue in Indonesia (B). Images credits: MEA Santos.

Distribution

Reproduction and Dispersal

As most species of Zoantharia are sessile, dispersal is primarily through the larval phase. There is little information about larval development, but aquarium experiments have revealed that the larvae of *Palythoa tuberculosa* are able to survive more than 3 months (Polak et al., 2011). The few published studies about sexual reproduction of zoantharians have been conducted mostly with shallow water species occurring in < 50 m depths. Overall, brachyncemic species appear to be generally hermaphroditic, while macrocnemic species are not (Ryland et al., 2000). For example, brachyncemic *P. caribaeorum* and *P. variabilis* were reported as sequential protogynic hermaphrodites in Brazil (Boscolo and Silveira, 2005), whereas macrocnemic *Epizoanthus couchii*, *Parazoanthus anguicomus*, *P. axinellae*, and *Savalia savaglia* were shown to be gonochoric (Ryland et al., 2000; Previati et al., 2010).

Asexual reproduction is common in sessile invertebrates and can improve their dispersal and survival at local and regional scales (Foster et al., 2007; Harrison, 2011; Capel et al., 2017). Accordingly, zoantharians can disperse via asexual reproduction and many modes are known for the genera *Acrozoanthus*, *Palythoa*, *Parazoanthus*, *Savalia*, and *Zoanthus* (Karlson, 1983; Ryland, 1995; Acosta et al., 2001, 2005; Previati et al., 2010; González-Muñoz et al., 2019). Common asexual reproduction mechanisms are edge fissions or release of polyp balls or clusters (Acosta et al., 2005; Previati et al., 2010; González-Muñoz et al., 2019). Edge fission occurs when a parent colony segregates a polyp group at the colony edge, and this is often observed under competition for space with other species. On the other hand, polyp balls are usually produced and detach in the center of large colonies with substrate irregularities such as shells (Acosta et al., 2005). The polyp balls can roll on the substrate and be dispersed by waves and storms, allowing these colonies clones to escape local selective factors and environmental stress (Acosta et al., 2005).

Furthermore, dispersal through rafting has been observed in groups closely related to zoantharians. Hydrocorals, scleractinian corals, and sea anemones can travel long distances attached to floating volcanic sea-rafting pumice (Jokiel, 1989, 1990; Bryan et al., 2004, 2012) or man-made objects (Hoeksema et al., 2012, 2015). Likewise, brachyncemic and macrocnemic zoantharians are able to attach to different structures, including anthropogenic objects made of glass, nylon and metal that can float. Thus, it is possible that rafting plays a role in the distribution of Zoantharia (Santos and Reimer, 2018). In addition, some species of *Palythoa* and *Zoanthus* are hermaphrodites (Fadlallah et al., 1984), resilient against desiccation (Sebens, 1982; Rabelo et al., 2013), and have fertile polyps throughout the year (Boscolo and Silveira, 2005), indicating that these groups can have a high success as rafting riders (Santos and Reimer, 2018).

Zoogeography

Different species of Zoantharia occur across the world's oceans from the intertidal zone down to abyssal depths (Pax and Mueller, 1956; Burnett et al., 1997; Reimer et al., 2007a,b; Santos et al., 2019). Brachyncemic species are distributed in shallow waters of tropical to warm temperate seas (< 50 m for zooxanthellate species; Duerden, 1898, 1900; Carlgren, 1941; Reimer et al., 2007a,b, 2017a,b; while azooxanthellate *Sphenopus* is known until ~ 100 m depth; Kise et al., 2019). On the other hand, macrocnemic zoantharians have a more extensive distribution range as they also occur in temperate and polar oceans (e.g., Carlgren, 1927; Swain, 2010), and to greater depths (Carlgren, 1913; Carreiro-Silva et al., 2017; Reimer et al., 2019). Additionally, representatives of the family Abyssoanthidae have been reported down to ~ 5300 m depth (*Abyssoanthus convallis*; Reimer and Sinniger, 2010).

Although brachyncemic zoantharians are ubiquitous to shallow coral reef ecosystems, their zoogeographical patterns are poorly known. A recent study in the Atlantic Ocean revealed that these zoantharians have lower endemic rates than other common reef animals, as well as exceptionally wide distribution ranges (Santos et al., 2019). Likewise, some *Palythoa* and *Zoanthus* species in the Indian and Pacific oceans have extensive distributions (Hibino et al., 2013; Reimer et al., 2017a). Different than hydrocorals and scleractinian corals, which have generally deep genetic divergences between lineages of the Atlantic and Indian/Pacific oceans (Fukami et al., 2004; Arrigoni et al., 2018), there are sibling zoantharian species pairs between these two ocean regions (Reimer et al., 2012; Santos et al., 2016; Santos, 2019).

Furthermore, eight of the nine Zoantharia families are cosmopolitan, with the exception of Neozoanthidae that has so far been only reported from the Indian and Pacific region (Santos, 2019). Zoantharia have higher genera-level diversity in the Indian and Pacific compared to the Atlantic Ocean. Out of 28 total genera, 24 are found in the Indian and Pacific oceans, of which eight are endemic to this region (Santos, 2019).

Economic Importance

The pharmacognosy industry actively investigates Zoantharia, and has mainly focused on species of *Epizoanthus*, *Palythoa*, *Parazoanthus* and *Zoanthus* (Cariello et al., 1974; Moore and Bartolini, 1981; D'Ambrosio et al., 1997; Kuramoto et al., 1998; Miyashita et al., 2004; Cachet et al., 2009; Wilke et al., 2009; Ramos and Vasconcelos, 2010; Genji et al., 2010; Yoshimura et al., 2012; Rocha, 2013; Cen-Pacheco et al., 2014; Guarnieri et al., 2018; Guillen et al., 2018; Matsumura et al., 2018). For instance, bioprospecting research has isolated molecules from zoantharians that show promising results in the treatment of osteoporosis (Kuramoto et al., 1998; Genji et al., 2010) and snakebites (Guarnieri et al., 2018).

Zoantharia species are also common in the aquarium hobby industry, in particular brightly colored morphotypes of *Palythoa* and *Zoanthus*, which can reach prices of up to 100 USD or more for single polyps. Additionally, some lineages of the family Parazoanthidae (e.g., *Kulamanamana haumeae*) are popular in the jewelry business and are commonly known as “gold coral” (Waller and Baco, 2007).

Research Trends

This article has highlighted the economical relevance and ecological importance of the order Zoantharia. Moreover, some zoantharian species have high dispersal potential and generalist strategies to survive in varying environments. Such attributes have enabled these zoantharians to have exceptionally extensive distributions at large geographical scales, and overall Zoantharia show low endemism rates compared to other common animals in reef ecosystems. Nonetheless, there is still a lack of zoantharian studies following research lines such as genomics and population genetics. Future studies should examine the connectivity of zoantharian populations across ocean basins. The identification of environmental barriers to gene flow of such a widespread group will increase the knowledge of adaptation in marine ecosystems, and this is also relevant to management strategies.

Acknowledgments

We thank I Kawamura, E Trinito, S Nakachi, and T Moritaki (Toba Aquarium) for kindly providing images used in Figs. 1B, 2D–F, respectively. The chapter editor MJ Costello is also thanked for comments that improved an earlier version of this article.

Abstract

The field of ecology has shifted from a relatively narrow focus on plant and animal populations and communities to more broadly understanding ecological patterns, processes and changes, including those shaped by interactions with human societies. This trend is embodied by the growth of research and scholarship investigating direct interactions between humans and environments: the science of coupled human and natural systems. Understanding global ecology and its modification through land use as the emergence of an anthropogenic biosphere composed of anthromes (anthropogenic biomes) allows for a synthesis of human-related ecological topics from local to global scales. In this article we introduce the section that shifts the perspective from biomes to anthromes, soundscapes, changing aquatic systems, and pressures of energy development on land cover.

Introduction

The global patterns of life on Earth have been described in relation to variations in climate, terrain and soils since at least the time of Alexander von Humboldt's work in the late 18th century (Schrodt et al., 2019). In 1939, Richard Carpenter wrote in "The Biome" about Clements' 1916 paper proposing the term biome itself as "a biotic community consisting of both plants and animals." More than 50 years after Clements, in 1962, Robert Whittaker published his "Classification of Natural Communities" framing global vegetation patterns and biomes as a function of temperature and precipitation, providing a framework still widely used to understand the global patterns of terrestrial ecology. Just over 40 years later, anthropogenic biomes or anthromes were conceptualized by Ellis and Ramankutty (2008) to characterize the global patterns of ecology shaped by human societies.

In conceptualizing anthromes, Ellis and Ramankutty, like Whittaker, used an empirical approach to assess ecological patterns at global scale. Unlike both Clements and Whittaker, they recognized and incorporated direct and sustained human interactions with the biotic communities and more broadly human interactions with ecosystems. Thus they shifted the framework for ecology from the classic model of vegetation patterns shaped by climate to the model of an anthropogenic biosphere in which human societies shape heterogeneous and multifunctional landscape mosaics of used, remnant and novel habitats that vary in response to land-use system, land use intensity and population density (Ellis et al., 2010; Ellis, 2015). As a consequence, researchers, students, and practitioners can now visualize and interact with maps and data quantifying how more than three-quarters of Earth's ice-free land surface has been transformed into dense settlements, villages, croplands, rangelands, and seminatural lands as well as the wildlands still remaining without intensive use. Though fragments of ecosystems and habitat representing the classic biomes are still embedded within most anthromes, and nearly one quarter of Earth's land remains as wildlands, the multifunctional mosaic landscapes of anthromes have largely transformed or replaced the biomes and ecosystems described in the other volumes in this Encyclopedia.

This reframing of global ecology to incorporate the realities of an increasingly human world has created an intellectual space for linking broader concepts across ecology, conservation, and sustainability science (Martin et al., 2014). Indeed, during these last 10 years, anthrome frameworks have been used or cited across a diversity of disciplines (Fig. 1). Building on this collection of manuscripts in this volume we see these connections via chapters focused on the intensively used, seminatural, and wild anthromes. The thread of direct human interaction with the environment is maintained across subsequent chapters extending to marine and aquatic systems, the acoustic spaces we are all embedded within, and lastly, specific applications and local case studies of coupled human and natural systems (Quinn and Quinn, 2020a) that shape and are shaped by the landscape.

The first four chapters present either a global summary or application of anthromes. Ellis 2020 provides a summary of the development of anthromes and challenges the reader to consider or reconsider the focus of earth stewardship in the Anthropocene. With a historical perspective and an updated anthrome dataset, Goldewijk (2020) provides a review of how the anthrome classifications provide a valuable lens on historical patterns. The article provides a reconstruction of global changes in anthrome distribution from 10,000 BCE to 2015 CE and evidence of temporal and regional heterogeneity in land cover change. Land-use intensity is one important input for the anthrome classification. Andersen and Quinn (2020) provides a review of Human Appropriation of Net Primary Production (HANPP), focusing on global, regional, and watershed scale patterns of land-use intensity via HANPP. In addition,

Fig. 1 Journal classifications and citation counts, via 2019 Web of Science search, of papers that cite anthromes and associated literature.

he begins to explore spatial correlations between HANPP and anthromes. Lastly, [Cook and Quinn \(2020\)](#) review plant and vertebrate biodiversity patterns across anthromes, highlighting overlooked conservation spaces in used anthromes.

The subsequent four chapters review natural and human systems of dense settlements, villages, and seminatural (in particular residential and populated woodlands) anthromes. These anthromes are home to the greatest number of people (an average population density of 258 persons km^{-2}) and over 40% habitat loss on only 17% of ice-free surface ([Ellis et al., 2010](#)). Thus, the relationship and interactions between human and natural systems here are close and complex. Vogt provides a trio of chapters about urban systems ([Vogt, 2020a,bc](#)) and specifically forests across urban, mixed settlements and semi-natural woodland anthromes. Vogt also addresses the biophysical ([Vogt, 2020b](#)) aspects of urban forest characteristics and how they may be similar or different from our naive assumptions of what a forest is. Building on this description she reviews the benefits of ecosystem services of urban forests and tools to estimate their value. However, because these forests are embedded in anthromes, Vogt provides a review of urban forests and social-ecological systems ([Vogt, 2020a](#)), in particular discussing actors (e.g., residents; stormwater management districts; real estate developers and builders; property management companies, among others), ownership, distribution of the benefits discussed in the previous chapter, costs of their maintenance, and perhaps more importantly, how there is heterogeneity and often a lack of spatial (and perhaps temporal connection) between benefits and costs of trees and forests in these used and seminatural anthromes. [Unnikrishnan and Nagendra \(2020\)](#) use Bangalore, India as a case study to demonstrate how nature and society have “shaped, transformed, and influenced each other’s trajectories of development” in dense settlements and villages with a particular focus on the role of urban water bodies, colonization, and the urban commons. They conclude, much like Vogt, that as we look forward that the future is equitable and just. Shifting towards more traditional urban ecology, [Parsons and Backe \(2019\)](#) review trophic interactions between trees, herbivores, and natural enemies in used and seminatural anthromes. In their consideration of arthropod invasion dynamics, biotic homogenization, and urban species distributions they highlight the dynamic nature of ecology in used anthromes.

Cropland and rangeland anthromes are globally extensive anthromes, together encompassing almost 50% of ice-free surface ([Ellis et al., 2010](#)), though generally with lower population densities than the anthromes discussed above. Rangeland, the most extensive anthrome, is addressed by [Schallner et al. \(2020\)](#). In particular, they review the capacity of rangelands to provide ecosystem goods and services in the face of increasing demand on these lands. With a focus on global arable land, [Quinn \(2020\)](#) uses the anthrome data set to describe patterns of cropland anthromes and the importance of cropland to global and regional biodiversity conservation. Given the frequency of trees in cropland anthromes, [Gold \(2020\)](#) provides a valuable review of the patterns and value of agroforestry; farming and food systems where trees and agriculture are integrated to optimize multiple ecological and economic functions, for both temperate and tropical regions. More regionally focused, [Ricard et al. \(2019\)](#) provide a case study of agroecology in the Pampas of Argentina, calling for adaptive, science-based management to help maintain agricultural productivity while maintaining biotic and abiotic ecological processes. [Ferrara et al. \(2019\)](#) highlight the importance of heterogeneous agricultural landscapes for both ecosystem function and cultural ecosystem services. The call for place-based and practice-based stewardship in the future that is reflective of heterogeneous cultural landscapes. Lastly [Hölting et al. \(2019\)](#) define and discuss the importance of multifunctionality across working landscapes highlighting how a better sense of the valuation of multifunctionality could improve how we manage landscapes.

Moving away from the anthromes with the greatest direct impact of humans, [Allan et al. \(2020\)](#) review global wildlands including discussions of definitions, origins, and applications of the term. They link and build upon recent mapping efforts of wilderness defined as “pressure free lands with a contiguous area > 10,000 km² for the years 1993 and 2009” with the spatial classification of anthromes by [Ellis et al. \(2010\)](#). They find, perhaps not surprisingly, a high level of spatial congruence between the defined wilderness areas of [Allan et al., 2017](#) and the statistically defined wilderness of anthromes; though a clear difference is evident in the rangelands of Australia and Mongolia. In addition, for readers interested more broadly in wildlands and wilderness, it is worth noting the discussion wilderness provided by [Speitz \(2019\)](#) in the following section on the complexity of our definitions and application of wilderness. Building on traditional ideas of wilderness and conservation and more recent discussions on conserving half the earth for conservation, [Boyle \(2019\)](#) discusses how anthromes vary within and across protected areas, highlighting the frequency of used anthromes embedded in many protected areas.

Moving beyond the specific framework of anthromes, subsequent chapters review other ways that humans’ direct and sustained interactions with the biosphere have shaped the environment. [Hanks \(2020\)](#) provides a comprehensive assessment of the impacts of dams on river structure and function and consequently human systems. The heterogeneity in placement and value of the over 16 million dams adds complexity to their management and sustainability. Moving from freshwater to marine systems, [Roark \(2020\)](#) and [Boonstra et al. \(2019\)](#) review two interactions that result in direct sustained impacts on marine systems. [Boonstra et al. \(2019\)](#) focus on the coupled human-natural system of small-scale fisheries in the Global North and South. In their review, they point out how small-scale fishing systems are shrinking under multiple pressures and may serve as an essential biocultural refugium. [Roark \(2020\)](#) reviews the drivers of and sustained impacts of endocrine disruptors in marine systems, focusing on how these persistent environmental contaminants can result in reproductive, developmental, metabolic, or behavioral dysfunction in marine organisms.

Capturing an emerging space in how humans interact with and shape the environment, [Happel and Happel \(2019\)](#) review the field of soundscape ecology. In particular, they document the development of the field, key concepts including biophony, geophony, and anthrophony, and the impacts of human noise on the ecosystem and species health. In a more focused review, [Oden et al. \(2019\)](#) discuss the pervasive impacts of roads on avian vocalizations. An expanding energy portfolio to include renewable sources has resulted in a broader scale direct impact of energy on land use and land cover. Addressing this emerging driver of change, [Pereira et al. \(2019\)](#) and [Basudde \(2020\)](#) link the development of energy and land-use policies. Given the global and growing footprint of energy development, their local case studies in Brazil and Uganda serve as a good starting point for future scenarios and discussion. The section ends with two focused case studies from the US National Park Services. [Spies et al. \(2019\)](#) and [Phillipson et al. \(2019\)](#) each provide a status assessment from island regions (Hawai’i and the Mariana Islands Archipelago) shaped by development. In particular, they consider the impacts of the regions current ecological status, key stressors, conservation efforts, and future viability in the region.

Conclusion

This section captures some of the ways that human interactions shape terrestrial and aquatic environments. Pollution and runoff, desertification, invasive species, road networks, agriculture, and many other factors are all impactful and pervasive. But as a collection, these chapters help us understand the environments we live and work within. Moreover, by emphasizing the links and feedbacks between natural and human systems ([Quinn and Quinn, 2020a](#)), they suggest that anthromes serve as a bridge in this Encyclopedia and more broadly in scholarship and practice between biomes and sustainability science and human systems ([Quinn and Quinn, 2020b](#)).

Abstract

Human societies and their use of land have transformed ecology across this planet for thousands of years. As a result, the global patterns of life on Earth, the biomes, can no longer be understood without considering how humans have altered them. Anthromes, or anthropogenic biomes, characterize the globally significant ecological patterns created by sustained direct human interactions with ecosystems, including agriculture, urbanization, and other land uses. Anthromes now cover more than three quarters of Earth's ice-free land surface, including dense settlements, villages, croplands, rangelands, and seminatural lands; wildlands untransformed by agriculture and settlements cover the remaining area.

Introduction

Human societies and their use of land have transformed ecology across this planet for thousands of years (Ellis, 2015; Stephens et al., 2019). As a result, the global patterns of life on Earth, the biomes, can no longer be understood without considering how humans have altered them. Anthromes, or anthropogenic biomes, characterize the globally significant ecological patterns created by sustained direct human interactions with ecosystems, including agriculture, urbanization, and other land uses (Ellis and Ramankutty, 2008). Anthromes now cover more than three quarters of Earth's ice-free land surface, including dense settlements, villages, croplands, rangelands, and seminatural lands; wildlands untransformed by agriculture and settlements cover the remaining area.

Look out of any airplane window or at imagery from any Earth satellite and the signs of human transformation are everywhere. From the farms, grazing lands, plantations and managed forests that sustain our societies to the settlements and cities where we live and the roads, railroads and paths that crisscross the continents and connect us all together. Using spatial data from remote sensing, government statistics, and other sources, these global fingerprints of human societies, including human-altered vegetation cover, built structures, crops, livestock grazing, irrigation, roads and the varying densities of human populations can be brought together, characterized, and mapped using Geographic Information Systems (GIS). The first such effort in this direction, the Human Footprint, used these data to assess human influences on ecology as a single number varying from high to low (Sanderson et al., 2002). But is it truly possible to capture the rich diversity of human transformation of ecology across this entire planet using a single number?

In 2008, Ellis and Ramankutty set out to map the globally significant patterns of human altered and managed ecosystems through a statistical approach called cluster analysis (Ellis and Ramankutty, 2008). Using this approach, the globally significant patterns of human shaped ecosystems could be mapped from data on human populations, land use and vegetation cover, just as the natural biomes, in all their rich diversity from tundra to tropical rainforests, are mapped relation to the globally significant patterns of climate, terrain, and other natural environmental conditions. In 2010, this approach was updated to allow anthromes to be mapped globally over time, from 1700 to 2000 (Ellis et al., 2010). Anthrome maps based on this system of classification are now used widely in teaching, research and conservation (e.g. Chapin III et al., 2012; Martin et al., 2014; Merritts et al., 2014; National Geographic Society, 2014; Freeman et al., 2016; Miraldo et al., 2016; Dinerstein et al., 2017; Smith et al., 2019). Using this system of anthrome classification, five "levels" of are recognized and mapped globally, as described in Table 1 and illustrated in Fig. 1.

Anthromes and the Anthropogenic Biosphere

Urban and other dense settlement anthromes are the most highly transformed anthromes on Earth and sustain population densities well over 1000 persons per square kilometer in landscapes largely converted into settlements and other residential and industrial infrastructure. Village anthromes are also highly transformed and densely populated (above 100 persons per square kilometer), but their mostly agricultural landscapes sustain largely rural populations, often in regions inhabited and farmed since ancient times.

Table 1 Anthrome classes within five anthrome levels, with global areas for 2015 CE in square kilometers (percent in parentheses; based on Ellis et al., 2020; Fig. 1).

Area (%)	Name	Description
2,237,074 (1.7%)	Dense settlements: Urban and other nonagricultural dense settlements	
723,555 (0.5%)	Urban	Densely built-up environments with very high populations
1,513,519 (1.1%)	Mixed settlements	Suburbs, towns and rural settlements with high but fragmented populations
9,365,333 (7.1%)	Villages: Densely populated agricultural settlements	
1,078,848 (0.8%)	Rice villages	Villages characterized by paddy rice
1,974,819 (1.5%)	Irrigated villages	Villages characterized by irrigated crops
5,436,990 (4.1%)	Rainfed villages	Villages characterized by rainfed agriculture
874,677 (0.7%)	Pastoral villages	Villages characterized by pasture and rangeland
19,379,053 (14.7%)	Croplands: Lands used mainly for annual crops	
1,048,619 (0.8%)	Residential irrigated croplands	Irrigated croplands with substantial human populations
9,998,304 (7.6%)	Residential rainfed croplands	Rainfed croplands with substantial human populations
5,550,446 (4.2%)	Populated rainfed croplands	Croplands with significant human populations
2,781,684 (2.1%)	Remote croplands	Croplands without significant populations (irrigated and rainfed)
34,900,571 (26.5%)	Rangelands: Lands used for pasture and livestock grazing	
6,905,141 (5.2%)	Residential rangelands	Rangelands with substantial human populations
10,656,903 (8.1%)	Populated rangelands	Rangelands with significant human populations
17,338,527 (13.2%)	Remote rangelands	Rangelands without significant human populations
31,963,461 (24.3%)	Seminatural lands: Inhabited lands with minor use for permanent agriculture and settlements	
4,302,009 (3.3%)	Residential woodlands	Forest biome regions with minor land use and substantial populations
7,342,981 (5.6%)	Populated woodlands	Forest biome regions with minor land use and significant populations
8,749,492 (6.6%)	Remote woodlands	Forest biome regions with minor land use without significant populations
11,568,978 (8.8%)	Inhabited treeless and barren lands	Regions without natural tree cover having only minor land use and a range of populations
33,958,547 (25.8%)	Wildlands: Lands without human populations or substantial land use	
15,399,162 (11.7%)	Wild woodlands	Forests and savanna
16,001,211 (12.1%)	Wild treeless and barren lands	Regions without natural tree cover (grasslands, shrublands, tundra, desert and barren lands)
2,558,174 (1.9%)	Ice, uninhabited	Regions covered by permanent ice
131,804,039 (100%)	Global land	

While these urban and village anthromes covered only about 8% of Earth's ice-free land in 2000 CE, more than 80% of Earth's human populations lived in them. Moreover, ongoing migrations from rural areas into cities are making urban anthromes even denser as human populations continue to concentrate into and expand Earth's relatively small but dynamic area of urban anthromes.

The farm fields that produce most of our food are mostly found in croplands anthromes. In some croplands, crops cover the land almost completely. More common though, are croplands formed of a complex mix of crops, settlements, and patches of tree cover and other less intensively managed habitats. Rangeland anthromes sustain grazing livestock and are the most extensive of the used anthromes. While these cover nearly one third of Earth's ice-free land, they also tend to be lower productivity areas that sustain relatively low population densities and are usually less transformed by human use. Seminatural anthromes are relatively lightly populated and used landscapes, with a majority of their areas composed of remnant and recovering habitats.

Wildlands without human populations or intensive use of land still cover nearly one quarter of Earth's ice-free land. Yet only about 20% of Earth's tree cover is in wildlands and more than one third of wildlands are in relatively barren regions, like deserts and tundra. As a result, wildlands account for only about 10% of Earth's terrestrial net primary productivity (NPP)—the photosynthetic production of plants that supports the rest of life on Earth—even less than one would expect based on their area. Remarkably, in 2000, the total area of wild forests remaining on Earth was less than the total area of densely populated village and urban anthromes. The same holds for NPP, with more net primary production occurring within the densely populated anthromes than in Earth's last remaining wild forests. More remarkable still, more than 25% of Earth's tree cover is embedded within cropland anthromes, a greater extent than the total area of forests remaining in wildlands. Clearly, the intensively used anthromes deserve serious attention in understanding Earth's ecology, and their global area and ecological importance are vast and growing.

Anthromes Are Mosaics of Used and Novel Ecosystems

While about 40% of Earth's land is used directly for crops, pastures and settlements, a nearly equivalent area is neither used directly for agriculture and settlements nor left behind in large wild areas without these uses. What is the ecology of these areas? The answer requires a deeper understanding of the way landscapes tend to be transformed and managed by human societies.

Fig. 1 Global map of anthromes in 2015 CE. Eckert Equal Area projection (Ellis et al., 2020).

Even within the most densely populated and intensively used anthromes, including urban areas and ancient village landscapes, humans rarely convert all land into agricultural and residential uses, but rather, selectively concentrate these uses in areas where they will be most productive, while also planting and retaining trees and other green spaces in association with settlements and infrastructure. When viewed from high above, we see urban areas and settlements embedded within seas of agricultural land, with patches of trees interspersed within and among croplands and residential areas, and managed vegetation is mixed with natural and seminatural vegetation. For this reason, anthrome landscapes tend to be more complex than those of the classic biomes, and are best characterized as heterogeneous multifunctional mosaics of different land uses and land covers, especially where terrain is complex and populations area dense.

Productive level terrain is generally the focus of agriculture and settlements, while hillier, drier, mountainous, and remote terrain tends to be left unused or less used, even when surrounding areas are used intensively. Patches of used land are often abandoned and left to recover within used anthromes, and even remnant patches of habitat within anthromes that have never been managed for production tend to become transformed by human influences ranging from more frequent fires and fire suppression, to harvests of fuelwood, timber and other natural resources, hunting, foraging, increased exposure to exotic species, pollution, and other human influences. Even the isolation of remnant patches from other habitat patches within the used landscape can alter rates of species extinctions and invasions. As a result of these pervasive human influences, even the least disturbed areas of anthrome landscapes generally have biotic communities and ecosystem processes that differ substantially and potentially irreversibly from their prior historical state, broadly fitting the definition of novel ecosystems (Hobbs et al., 2009; Ellis et al., 2010).

Thus considered at a landscape scale, the used and seminatural anthromes are multifunctional mosaics of ecosystems used for production, within which islands of remnant, recovering, and lightly used novel ecosystems are embedded (Fig. 2). For this reason, anthromes are far more than just the used areas of the planet. In fact, they retain a greater global area of lightly used habitats, about 37%, than the total area remaining as wildlands (around 23%). Moreover, these areas tend to be both ecologically productive and highly biodiverse, even though their habitats show clear legacies of human influence and their biological communities tend to be composed of novel assemblages of native, introduced and invading species (Ellis, 2013). The novel ecological patterns and process of anthromes, which now cover more than three quarters of Earth's terrestrial surface, represent the biosphere in its current, human-altered form, and provide the basis for an ecology of the anthropogenic biosphere (Ellis, 2015).

Fig. 2 Anthromes are heterogeneous landscape mosaics composed of used lands and novel ecosystems.

Ecological Science, Theory, and Education in an Anthropogenic Biosphere

Biomes are introduced as the fundamental units of the biosphere in nearly every introductory biology, Earth science, and environmental science textbook. While anthromes should not be thought of as a replacement for existing biome systems based on vegetation and climate, anthromes offer a more objective view of the terrestrial biosphere in its contemporary anthropogenic state. This new model of the biosphere moves us away from an outdated view of the world as “natural ecosystems with humans disturbing them” and towards a vision of “human systems with natural ecosystems embedded within them” (also known as social-ecological systems or coupled human and natural systems). This is a major change in paradigm for most natural scientists concerned with ecology and environments, but it remains a critical advance in efforts to better understand the biosphere as it exists today, and even in the deeper past. Increasingly, anthrome maps and global data on human transformation of ecology are helping to accomplish this, as part of basic curriculum in biology and ecology textbooks (Chapin III et al., 2012; Merritts et al., 2014; Freeman et al., 2016). Anthromes have also been called “human biomes,” a less precise term, and a related term, “indoor biomes” is also increasingly used (Martin et al., 2015).

From the basic theoretical view, the anthrome model of ecological pattern and process has implications for understanding the fundamentals of ecological science from global to regional and even local scales. This general understanding has been integrated within the theory of anthroecology which aims to investigate, understand, and address the ultimate causes of anthropogenic ecological change that shape the emergence of anthromes at global scale, and the ecological patterns, processes and dynamics within anthromes over time and under different social and ecological conditions (Ellis, 2015). Fig. 3 illustrates the different conditions of population density and land use under which the different anthromes form, and how these conditions in turn shape the patterns and processes of net primary production (NPP), carbon storage or emissions from soils and vegetation, reactive nitrogen (from both natural, agricultural and industrial processes), and the patterns of biodiversity in terms of species richness of both native and introduced species.

Efforts to deepen scientific understanding of the ecological patterns and processes shaped and sustained by human societies are ongoing at global, regional and local scales, including recent efforts to define a new “human age” of geologic time, the Anthropocene epoch (Ellis, 2011, 2015, 2018; Waters et al., 2016). Though the Anthropocene remains an informal term and a work in progress (Ellis, 2018), interest in better understanding human transformation of the biosphere is growing almost as fast as human societies are transforming the planet.

Fig. 3 Conceptual diagram illustrating patterns of populations, land use, novel habitats and biotic communities and ecosystem properties within and across anthromes.

Earth Stewardship in the Anthropocene

Human transformation of this planet is causing unprecedented and accelerating changes in Earth's ecology, from climate change to the massive losses of habitat that are causing species extinctions at alarming rates. While focusing on the negative consequences of human transformation of Earth can help to eliminate some of these, it is equally, if not more important, to focus on efforts to guide the unprecedented powers of contemporary human societies towards creating a better future for both people and nonhuman nature on the only planet we share; the vision of Earth stewardship (Chapin III et al., 2011; DeFries et al., 2012).

Now that humans have reshaped more than three quarters of the terrestrial biosphere into anthromes, the need to conserve biodiversity and nonhuman habitats in the working landscapes of anthromes is increasingly recognized as critical (Martin et al., 2014). Though wildlands are critical habitats for biodiversity conservation in large-scale protected areas, anthromes have largely replaced wildlands in Earth's most biodiverse and productive regions; the novel ecosystems embedded within anthrome landscapes now cover nearly twice the global area of wildlands. Even though many species are poorly adapted to living in close proximity with human societies (and vice versa), recent studies indicate that under appropriate conditions, most native taxa may be sustainable within anthromes, even while increasing anthrome productivity in support of human populations (Ellis, 2013; Quinn et al., 2014).

One key principle of sustainable ecosystem management in the anthropogenic biosphere of the Anthropocene is to develop and sustain beneficial or at least nonharmful interactions between human and nonhuman species and habitats, because avoiding these interactions entirely is simply not a practical strategy in most areas. In working towards more effective environmental governance strategies, anthromes can play a key role in moving conservation discussions beyond the outdated paradigm that human use of ecosystems merely "destroys" them. While there are certainly many examples of human degradation of ecosystems without any long-term benefits to anyone or any being, the conversion of natural habitats into farms, settlements and other infrastructure, creating anthromes, is the basis for sustaining human societies. There are better and worse ways to manage Earth's ecology, but the notion of "going back to nature" to sustain human populations is no longer an option.

Fig. 4 Earth stewardship in an anthropogenic biosphere. What kind of biosphere do “we” want?

Earth stewardship in the Anthropocene has to be about much more than just “preventing humans from destroying the planet.” The way forward will depend on visions of the future “we” want and strategies to get there: a future where people and nature can thrive together over the long term (Fig. 4). Yet there is no “we,” no singular “humanity” working the levers of planetary governance in the cockpit of spaceship Earth. Making this better future possible will require negotiations across our diverse populations of stakeholders, the “we,” who must work together towards these better futures—from farmers ranchers, urbanists and conservationists, to Indigenous Peoples and governments, nongovernmental organizations and international corporations. The challenges of creating a better future will require multi-level governance solutions that bring people together to negotiate productively across the global supply chains, producers, consumers and conservationists that are now shaping the biosphere (Ellis, 2019).

Do “we” want a sprawling world of human infrastructure that consumes most of Earth’s land, or a dense urban world that leaves plenty of shared and wild spaces to sustain the rest of life? The answer will come from all of us, and it will require much more than saving nature in places far away. Earth stewardship in the Anthropocene will mean governing anthromes to more effectively serve human needs while making space to sustain the rest of nature in an increasingly anthropogenic biosphere.

Abstract

Since mankind began clearing land and domesticating favored plants and animals at the start of the Holocene, the terrestrial biosphere has been transformed into anthropogenic biomes or anthromes. A first attempt to reconstruct global changes in anthrome distribution from 10,000 BCE to 2015 CE (the Anthromes12K dataset) was derived by using human population density and land use from the History of the Global Environment (HYDE) database (version 3.2), in combination with alternate anthromes classification schemes. At the beginning of the Holocene almost 40% of the Earth's land surface was classified as completely wild, without human settlement or agriculture. The remaining 60% was classified as seminatural with only minor areas of agriculture and settlements, where 33% of the seminatural class was classified as inhabited treeless and barren lands and 26% as remote woodlands.

The first significant areas of cropland and rangeland anthromes emerged around 1 CE (2%) slowly increasing to 5% in 1000 CE. Villages and dense settlements still occupied hardly any space that time (0.2%). The global extent of croplands and rangelands increased by agricultural expansion into wildlands and intensification of land use to 9.4% in 1700 CE and this process accelerated to the end of the 20th century to a share of almost 42%. Villages and dense settlements occupying 8% of the global land surface. All this happened at the expense of seminatural lands who decreased in area by 35.5% and wildlands who lost 14.5% of their original area. This transformation took not place evenly distributed over the Earth and over time, but varied greatly across regions and biomes, depicting large differences in the onset of agriculture.

Introduction

Humans have altered the face of the Earth's landscapes for thousands of years. The first hunter-gatherer cleared land through burning, then the emergence and spread of agriculture took place, leading eventually to the rise of large-scale urban industrial societies (Ellis, 2015; Ellis et al., 2013; Kirch, 2005; Smith and Zeder, 2013). Although the role of recent global populations and land use change in transforming Earth's climate received much attention lately (Foley et al., 2005), we cannot understand these processes without assessing their long-term dynamics in transforming the biosphere (Ellis et al., 2013).

These long-term dynamics can be assessed directly by applying existing historical reconstructions of land use and population, e.g. (Kaplan et al., 2011; Newbold et al., 2015; Ramankutty and Foley, 1999), or by emerging new datasets, such as charcoal and pollen, although these have not (yet) a globally coverage. One recently developed method of assessing the human transformation of the terrestrial biosphere is by mapping the transformation of the "natural vegetation patterns as shaped by climate, terrain and other biogeographic factors" (or classic biomes), into anthropogenic biomes (or anthromes). The idea is that human interactions with ecosystems shaped the global patterns of ecology (Ellis et al., 2010; Ellis and Ramankutty, 2008).

A rule-based classification system, first developed by Ellis et al. (2010), is used to map anthromes by integrating global datasets of human population and land use. In this study, the most recent version of the HYDE database version 3.2 was used (Klein Goldewijk et al., 2011). HYDE provides estimates for population, built-up area, cropland (irrigated and non-irrigated), rice, pastures and rangeland on a 5-arcminute resolution (85 km² at the equator).

Methodology

The potential natural vegetation map of [Prentice et al. \(1992\)](#) formed the basis of the pristine start situation, assuming no human interference at all. Then, an updated and modified rule-based anthrome classification model of [Ellis and Ramankutty \(2008\)](#) upon the new HYDE 3.2 global dataset of human land use was applied.

HYDE

HYDE is an internally consistent spatially explicit database describing the long-term development of human population and land use. Population is represented by 5' resolution maps of total, urban and rural population, as well as built-up area and population density, for the period 10 000 BCE to 2015 CE. The land use categories include croplands, with a distinction between irrigated and rain-fed crops (other than rice) and irrigated and rain-fed rice. Also, land used for livestock grazing is separated into two categories; more intensively used and managed pasture, and less intensively used rangeland. This was done in a two-fold manner to satisfy climate modelers which act upon these classification labels whether to convert the ecosystems or not. A more elaborate description is provided in [Ellis et al. \(2020\)](#).

The starting point for allocation of population and land use are reference maps for the year 2010 CE. The reference map for population was derived from [LandScan \(2014\)](#). The United Nations World Population Prospects ([UN, 2009](#)) provided population statistics for the post-1950 CE, and various country specific sources were applied, if available. The reference maps for cropland and grazing land were derived from the European Space Agency (ESA) consortium ([ESA, 2016](#)). See [Klein Goldewijk et al. \(2017\)](#) for an elaborate description of the selection criteria. The reference map for rice was created by combining data from the MIRCA database ([Siebert, 2008](#); [Siebert et al., 2015](#)), [Ricepedia \(2015\)](#) and maps from [You et al. \(2014\)](#).

The influence of these satellite-based reference maps for allocation weakens when modeling into the past, and some simple allocation rules take over. These rules combine a set of normalized maps of population density, soil quality, distance to water, slope and climate for croplands, and a combination of climate, potential biomes favorable for grazing (e.g. natural grasslands, savanna), net primary production and population density for grazing lands. Irrigation and rice are allocated default within the total cropland area.

Classification System

Anthromes version 2.1 basically replicates the original anthromes 2.0 approach of [Ellis et al. \(2010\)](#) by using grazing land (=pasture + rangeland) together as a direct substitute for the original, combined, "pasture" variable of the original HYDE 3.1 dataset. Anthromes v2.1 classification distinguishes 20 detailed anthrome classes grouped into five major categories: Dense settlements, Villages, Croplands, Rangelands, Seminalural lands and Wildlands (see [Table 1](#)).

Results and Discussion

The Global Scale

Humans started influencing their natural environment already thousands of years ago by using fire as a tool to open natural savannas and grasslands for hunting and early forms of agriculture. Slowly, people evolved to a more sedentary existence by domesticating crops and animals. This process took place over a long time, roughly 12000–6000 BCE and in several places in the world, for example, the Levant region, northern China and India, and Central America. This transition from hunters/gatherers to sedentary farming is often referred to as the Neolithic Revolution ([Goudsblom, 2002](#)). Until 5000 BCE, roughly 60% of the Earth consisted of seminalural land, while the remaining 40% can be classified as wildlands. However, large parts of the seminalural class consist of remote woodlands and inhabited treeless and barren land with very low population densities indeed ([Fig. 1](#)).

The first noticeable agricultural lands seem to appear roughly around 2000 BCE, still occupying a very modest 1% of the total global land area. At 1 CE, the Mayans flourished in Central America, the Han dynasty reigned in China, India went through its Middle Period and the Roman Empire emerged in Europe, which resulted in a more widespread of croplands and rangelands all over the world, but still occupying < 6% of the total land area ([Fig. 1](#)).

In the centuries that followed, apparently not much expansion of agricultural area took place. Notably, large parts of Europe were depopulated as result of the Black Plague and subsequently many rural areas were abandoned and left for regrowth of the original forests ([Bork and Lang, 2003](#)). A process that also took place in the Americas after the Europeans arrived in 1492 CE. Introducing not only livestock and different agricultural practices but also diseases such as smallpox and the flu, which resulted in a decimation of the native population in many regions. This must have had a large impact on the native ecosystems such as a large regrowth of native forests ([Nevle and Bird, 2008](#)).

The pace of agricultural expansion really increased in the early 18th century, roughly at the start of the Industrial Revolution. It was a time of worldwide exploration and colonization, and establishment of plantations in many regions. Mechanization in the first half of the 20th century replaced horsepower and boosted rapid clearing of large areas of natural ecosystems such as for example the Great Plains in the US. A major boost of agricultural growth happened after WWII driven by the mass application of artificial fertilizer and genetic improvement of crops, also referred to as the Green Revolution or the Great Acceleration. All this is manifested by

Table 1 Anthrome version 2.1 classification scheme.

Dense settlements: Urban and other dense settlements

11 Urban Dense built environments with very high populations

12 Mixed settlements Suburbs, towns and rural settlements with high but fragmented populations

Villages: Dense agricultural settlements

21 Rice villages. Villages dominated by paddy rice

22 Irrigated villages. Villages dominated by irrigated crops

23 Rainfed villages. Villages dominated by rainfed agriculture

24 Pastoral villages. Villages dominated by rangeland

Croplands: Lands used mainly for annual crops

31 Residential irrigated croplands. Irrigated cropland with substantial human populations

32 Residential rainfed croplands. Rainfed croplands with substantial human populations

33 Populated rainfed croplands. Croplands with significant human populations, a mix of irrigated and rainfed crops

34 Remote croplands. Croplands without significant populations

Rangelands: Lands used mainly for livestock grazing

41 Residential rangelands. Rangelands with substantial human populations

42 Populated rangelands. Rangelands with significant human populations

43 Remote rangelands. Rangelands without significant human populations

Seminatural lands: Inhabited lands with minor use for permanent agriculture and settlements

51 Residential woodlands. Forest regions with minor land use and substantial populations

52 Populated woodlands. Forest regions with minor land use and significant populations

53 Remote woodlands. Forest regions with minor land use without significant populations

54 Inhabited treeless and barren lands. Regions without natural tree cover having only minor land use and a range of populations

Wildlands: Lands without human populations or substantial land use

61 Wild woodlands. Forests and savanna

62 Wild treeless and barren lands Regions without natural tree cover (grasslands, shrublands, tundra, desert and barren lands)

63 Wild, remote, ice

**Fig. 1** Transformation of anthromes over time.

the increase of the cropland and rangeland anthromes, at the cost of mostly the semi natural lands, and to a lesser extent the Wildlands (see Fig. 2).

After the Second World War the world's population increased exponentially. More and more people started to live in cities and towns, in 2008 CE more people on the planet lived in villages, towns and cities than on the countryside (UN, 2018). However, the share of Villages and Dense settlements is still very modest, it occupies around 0.5% of the Earth's total land area, although there are some places with higher levels (NW Europe, parts of India, China; Figs. 2 and 3).

Fig. 2 Anthromes v2.1 development over the 12k period, with two snapshots for the 10k BCE–1500 CE and 1500–2015 CE period.

Fig. 3 Anthromes v2.1 development in selected time slices showing the transformation of the different anthromes classes into each other. A clear increase of human dominated classes Dense settlements, Villages, Croplands and Rangelands at the costs of Seminatural lands and Wildlands.

Regional aggregated Anthromes (in million km²)

Fig. 4 Regional anthromes development over time (note the different Y-axes).

The Regional Scale

The transformation of biomes was not evenly distributed over time and space. Some regions transformed earlier than others, and some biomes were converted much more than others. All regions had quite a share of wildlands at the start of the Holocene, but some more than others. Oceania still had 65% wildlands back then, comparable to the 60% of former USSR, Canada and the United States, and the Middle East, North Africa and Turkey (MENAT) region, the rest was seminatural. Latin America and sub-Saharan Africa had less wildlands left (around 20%), Asia and Europe (~10%), the rest was already seminatural, but not densely populated. Canada and the United States and the former USSR still have a fair share of wildlands left (~60%), mainly boreal forest and arctic tundra, comparable with MENAT and Oceania, mainly barren and hot deserts.

Also, the start of agricultural development is not evenly distributed around the world. It was much earlier in MENAT, Asia, and Europe, where domestication of plants and animals took place as early as 9000–6000 BCE. The share in cropland dominated Europe from 1 CE onwards, while in Asia the increase in cropland and rangelands developed simultaneously until the onset of the 18th century, when rangelands expanded faster than croplands. Both regions saw an early growth of villages and dense settlements then other anthromes.

Developments were much different in the so-called New world. The regions of Oceania, Canada and the United States and Latin America experienced relative recently, that is, over the past two centuries, a significant increase in croplands and rangelands. Although native populations in those regions, especially in the Americas, already for a long time had practiced agriculture, it apparently was on such a modest scale that is hardly does shows up in analysis such as [Klein Goldewijk et al. \(2017\)](#). Recent evidence suggests that those studies might have severely underestimated the number of people and their agricultural presence in the pre-Columbus period. In Oceania the Aborigines did not practice sedentary agriculture, they were hunters and gatherers. In Sub-Saharan Africa Rangeland existed since 1 CE and occupies at present a relatively large share of the total anthromes scheme (ca. 50%), comparable with Oceania ([Fig. 4](#)).

Spatially, the anthromes wildlands category resides predominantly the higher latitudes such as the arctic and Antarctic regions, but also the hot desert areas such as the Sahara, Namibian and Australian deserts. The reminder of the world was at the beginning of the Holocene in a Seminatural state, either treeless and barren (fUSSR, MENAT), remote populated (fUSSR, Latin America) or populated at various levels (Europe, India, China). Around 1700 CE rangelands had established themselves in sub-Saharan Africa, Europe, and parts of (central) Asia, e.g. Western China and Mongolia. The most people living in Villages and Dense settlements were prominent in large parts of Europe and in the large river basins in India and China, see [Fig. 5](#).

Fig. 5 Anthrome maps over the Holocene, selected years.

Fig. 6 Percentage change of natural and anthropogenic biomes over time.

The Biome Scale

All these expansions of human influence must have had an impact on the natural ecosystems. One way of dealing with this is looking at biomes. Biomes are defined as a large naturally occurring community of flora and fauna occupying a major habitat, e.g. forest or tundra. As we look at the largest change we see that this mostly happened in the last five centuries, and especially in the open grasslands and savanna class (no. 9) which occupied 14.5% of the total land area in 10k BCE and 5.9% in 2015 CE, a loss of 8.6%. The second largest loss occurred in cool grasslands & steppe class (no. 10) which went from 10.8% to 3.2%, a loss of 7.6%. Open shrublands (class 12) lost 5%, Closed shrublands (class 11), Hot deserts (class 14), Tropical rainforests (class 1) and Tropical woodlands (class 2) all lost 2 to 3% of their original area. The other categories lost <2%. If we translate this to forest versus non-forest it yields a 9.8% loss in forests, and 27.6% in non-forested area, so surprisingly to some most of the transformations took place not in forests but in grasslands. The transformation of the natural biomes is depicted in Fig. 6.

Nevertheless, some regions still suffered a considerable loss of forest area. Europe, Asia and MENAT lost 40% or more of their original forest biomes during the Holocene. SSA, Oceania and Latin America lost between 22% and 30%, while the United States and Canada in North America and fUSSR lost less than 13% from their (large) original forest area, see Table 2. One has to be aware that the overall number can be a bit misleading. For example, the number does not reflect the large deforestation and reforestation waves in the United States during the 19th and 20th centuries. The change in the non-forested biomes is even larger in all regions except MENAT (dominated by the Sahara Desert). In the rest of the world's regions more than half of the original biomes has been transformed to other types of use, mostly the natural grasslands and savannas. They were often converted into croplands or rangelands. In some regions the deforestation trends have been reversed recently, the so-called forest transition. Coupled to a relative high standard of living, income, GDP some countries could afford to abandon prime agricultural area and let them regrowth or replanted to forest again. Examples are the United States, Japan, and Europe.

Conclusion

To conclude, a long term anthromes dataset for the Holocene has been produced. It shows a slow but steady development over time of human encroachment towards the wild, uninhabited regions of the world. This expansion of anthropogenic land use resulted first

Table 2 Forest and Non-forest transformation 10k BCE–2015 CE.

	Forest	Non-forest
Canada and USA	–13%	–45%
Latin America	–22%	–57%
Europe	–40%	–46%
fUSSR	–9%	–51%
N. Africa, M. East, Turkey	–45%	–31%
Sub-Saharan Africa	–30%	–50%
Asia	–40%	–59%
Oceania	–29%	–51%

in conversion of natural ecosystems, mainly natural grasslands, savannas and forests. The expansion of agriculture happened at a rather slow pace, varying per region in magnitude and timing. It accelerated in the past three hundred years but seem to slow down recently. At the same time, we also witnessed in the more densely populated areas more and more intensification of human land use activities.

Appendix A: Anthromes Classification Flowchart

Anthromes v2.1 classification algorithm. Same as Anthromes 2.0, with four changes. First, the grazing variable is substituted for the HYDE 3.1 pasture variable, because HYDE 3.2 now separates the HYDE 3.1 pasture variable into separate pasture = % area covered by intensively managed pastures) and rangeland = extensively managed grazing areas; grazing = pasture + rangeland. Second, land variable classifies cells with land area > 0 (anthromes v2.0 did not include cells without land). Third, a new anthrome class = 63 = ice, uninhabited is added; anthromes 2.0 included only ice-free land. Fourth, a no data anthrome class is added = 70 (used only as a placeholder for no data values after classification).

Appendix B: Regional Breakdown

Since HYDE is used as one of the inputs for the Integrated Model to Assess the Global Environment; IMAGE (Stehfest et al., 2014), all computations have been performed following the IMAGE regional breakdown. For simplification we aggregated the IMAGE regions into nine Anthromes regions.

Reg. no	Anthrome region	IMAGE regions	Land area (km ²)	% of total land area
1	North America	Canada	8,918,000	6.8
		USA	9,078,798	7.0
2	Latin America	Mexico	1,943,090	1.5
		Rest Central America	735,115	0.6
		Brazil	8,442,870	6.5
		Rest South America	9,184,572	7.0
3	Europe	Western Europe	3,625,136	2.8
		Central Europe	1,337,584	1.0
4	M. East, N. Africa and Turkey (MENAT)	Middle East	5,173,031	4.0
		Northern Africa	6,014,386	4.6
		Turkey	775,569	0.6
5	sub-Saharan Africa (SSA)	Western Africa	11,350,296	8.7
		Eastern Africa	5,849,409	4.5
		South Africa	1,219,090	0.9
		Rest Southern Africa	5,600,266	4.3
6	former USSR	Ukraine +	824,610	0.6
		Asia-Stan countries	3,888,675	3.0
		Russia +	16,517,548	12.7
7	Asia	India	3,164,144	2.4
		Korea	236,430	0.2
		China +	10,886,215	8.4
		Southeastern Asia	2,576,856	2.0
		Indonesia +	2,415,585	1.9
		Japan	421,313	0.3
		Rest of South Asia	184,3407	1.4
8	Oceania	Oceania	8,034,489	6.2
9	Greenland	Greenland	312,914	0.2
	World (without Antarctica)		130,369,398	100.0

Abstract

Human transformation of the planetary landscape is extensive and may have exceeded the land system change planetary boundary. The human appropriation of net primary production (HANPP) method models the intensity of human pressure on the landscape at different scales. Globally, HANPP has doubled since 1900 and currently humans appropriate about 25% of the total net primary production of the planet. HANPP spatially correlates well with anthropogenic biomes, as “used” anthropogenic biomes generally correlate with high HANPP. In addition to the global scale, the HANPP method can also be used at regional, national, and local scales, though extrapolation of datasets from one scale to the next should be carefully considered. Embodied HANPP is used to better understand the effect of imports and exports, and shows that HANPP generally is transferred from rural to urban populations. As a model, HANPP does have a relatively high level of uncertainty, but appears to be an important measure of land transformation.

Introduction

Although scientific concern regarding human alteration of the landscape has a long history, the extraordinary scale of environmental change became very apparent only in the last 25 years. Vitousek et al. (1997) showed the transformation of the planetary surface for the benefit of humans (e.g., Kareiva et al., 2007) was spatially extensive and had major impacts on global systems such as biodiversity and biogeochemical cycles. Later, Foley et al. (2005), Ramankutty et al. (2008) and others showed that row crop and pasture covered nearly 40% of the ice free planet. The subsequent delineation of the planetary landscape into anthropogenic biomes (anthromes) showed that over 58% of the planet is “used,” much of the rest is semi-natural, and less than 20% wild. Most of the “used” anthromes are directly associated with producing food via the village, row crop, and rangeland anthromes (Ellis, 2011). About 30% of the used anthromes of the planet are utterly transformed landscapes—high density settlements, villages, and croplands. The recent planetary boundary concept (Rockström et al., 2009; Steffen et al., 2015a) indicates that land use change has likely surpassed their definition of the boundary, though the choice of forest cover for the of the boundary by Steffen et al. (2015a) is somewhat controversial.

Regardless of the definition of the land-system change boundary, human conversion of the landscape typically reduces net primary production, the uptake of carbon by plants and other autotrophs minus energy lost via respiration, metabolism, and maintenance. As anthromes reflect human use of potential vegetation and land use intensity, a correlation between anthrome classification and change of net primary production seems likely. To address the uncertainty in the land-system boundary, Running (2012) proposed that the human appropriation of net primary production (HANPP) method could be used as a planetary boundary as it integrates the land-system change, freshwater use, biosphere integrity, and biogeochemical flow boundaries. But what is HANPP and how does it link to anthromes and land-use change?

The HANPP Method

Human appropriation of net primary production or HANPP is a measure of land use *intensity*. In effect, it is a measure of how humans transform the landscape to provide food, shelter, and transport. The domestication of the landscape, however, requires a

trade-off in that humans replace the vegetation that could potentially grow with different vegetation that can be harvested and grazed or with infrastructures such as buildings and roads. In effect, humans *appropriate* net primary production of the landscape because of land use change, harvest of biomass (crops, timber, forage, animals), and sometimes fire. Haberl et al. (2014) suggest HANPP is an “integrated socio-ecological indicator quantifying effects of human-induced changes in productivity and harvest on ecological biomass flows.” They suggest that HANPP is a valuable quantitative socioecological indicator that captures in a measurable and comparable way how humans transform and domesticate the landscape to meet our needs. The consideration of land use intensity also suggests anthromes and HANPP may have a close spatial association.

In general, HANPP is calculated by comparing the potential NPP of the defined landscape’s potential vegetation at a given time to the actual NPP of the landscape while accounting for harvest of crops and grazing of pastures and rangelands (Haberl et al., 2007, 2014). The basic equation for calculating HANPP is the following (Eq. 1, Fig. 1):

$$\text{HANPP} = \text{NPP}_{\text{pot}} - (\text{NPP}_{\text{act}} - \text{HANPP}_{\text{harv}}) \quad (1)$$

In this equation, NPP_{pot} is the potential net primary production of the landscape, NPP_{act} is the estimated NPP of the landscape as it exists, and $\text{HANPP}_{\text{harv}}$ is the NPP appropriated by harvesting of crops and timber and grazing by animals. $\text{HANPP}_{\text{harv}}$ includes “used extraction” (HANPP_{uc}) and the unused fractions associated with harvest such as residues left on the fields, roots of trees and crops left behind, and human induced fires. The difference between NPP_{pot} and NPP_{act} is $\text{HANPP}_{\text{luc}}$, or how much NPP is appropriated by land use change. NPP in each part of the equation can refer to either above ground NPP or to total NPP (above ground growth plus growth of roots below ground), and thus above ground or total HANPP. Generally, HANPP is reported as a percentage of NPP_{pot} , though it is also reported in mass of carbon per year appropriated (Haberl et al., 2007). These variables used in calculating HANPP (Haberl et al., 2014) are explained below in an introductory manner. Haberl et al. (2014) contains an excellent history of the development of the HANPP concept. A full discussion of methods and their limits are contained in Haberl et al. (2007), Erb et al. (2009), and Haberl et al. (2014).

Potential Net Primary Production: NPP_{pot}

The estimated net primary production of the landscape under a given climate condition in the absence of human land use is called the *potential* net primary production. Numerous methods exist for estimating potential net primary production, including large scale computer simulation models that account for multiple variables to simpler models that account for only rainfall and temperature (see Haberl et al., 2007, 2014; Andersen et al., 2015). These models are calibrated against actual measured net primary production of vegetation in various biomes reflecting potential vegetation. The choice of model depends on the nature and scale of the research problem. For example, at the global scale, the LPJ model is typically used (Haberl et al., 2007; Krausmann et al., 2013). In contrast, Andersen et al. (2015) in a study of HANPP at the watershed scale chose a very simple model to calculate NPP_{pot} based on temperature and rainfall. At each scale, data is lost when simplifying the spatial heterogeneity of potential vegetation. The model chosen should reflect the scale of the analysis and the availability of local data on net primary production.

Fig. 1 A conceptual model of the human appropriation of net primary production (HANPP). NPP_{pot} is the model estimate of potential net primary production (NPP), NPP_{act} is actual NPP of land cover types in the landscape, NPP_{luc} is NPP loss caused by land use change, NPP_{harv} is NPP of harvested timber and vegetation for crops and grazing, and NPP_{eco} is the NPP remaining in the landscape ecosystem postharvest. Modified from Haberl H, Erb KH, and Krausmann F (2014) Human appropriation of net primary production: Patterns, trends, and planetary boundaries. *Annual Review of Environment and Resources* <https://doi.org/10.1146/annurev-environ-121912-094620>.

Actual Net Primary Production: NPP_{act}

The actual NPP of the landscape is more difficult to estimate because real landscapes typically are a mosaic of different land uses. For example, a region can be a complex mixture of forest, low-density housing with turf grass and sparse trees, and row crop. Estimating NPP_{act} at finer grains requires knowledge of (1) the area of different land use and cover types, and (2) the NPP of the vegetation of the different land use and cover types.

At smaller scales, the land use and land cover of an area are typically classified using data from either satellite imagery or air photos depending on the scale of the research problem. For example, a global scale study of HANPP done at the 5' scale would require satellite imagery, but a watershed scale study could use airphotos or satellite imagery with a smaller grain (e.g., 30 m Landsat data). GIS databases, such as the USDA Cropscape or the US National Land Cover Database, can be used to get the area of a particular land cover rather than classifying oneself, but smaller land cover elements including single trees or smaller roads may be lost at this resolution. As Haberl et al. (2014) notes, the derivation of land cover datasets is difficult and time consuming because of the need for the areas for each pixel in the area of interest must total 100% and the total of all the pixels should align with that for the known land cover of the area of interest (this works primarily for state or national level where land cover data is available).

Once the land cover is classified, calculating the NPP_{act} for an area is difficult as it requires the use of data from the literature regarding ecologically similar landscapes or models (e.g., the LPJ model, Haberl et al., 2014). For forests and grasslands, data can be extrapolated from the literature or derived from vegetation models. Ideally, these data come from as similar an ecoregion as possible, but when local data is not available, regional is preferred to global. Vegetation models such as the LPJ model can also account for soil degradation and irrigation. For croplands, NPP_{act} is derived from crop harvest data typically collected and or made available at the national, state, or county level (e.g., Haberl et al., 2007; Andersen et al., 2015) using a variety of crop and harvest indices. More difficult are residential and urban lands that have complex mosaics of shrubs, trees, turf grass, and impervious surface. Such a mosaic has a complex mixture of NPP ranging from impervious surface at $0 \text{ g C m}^{-2} \text{ yr}^{-1}$ to turfgrass at $1000 \text{ g C m}^{-2} \text{ yr}^{-1}$ to forested areas of over $1000 \text{ g C m}^{-2} \text{ yr}^{-1}$ (Andersen et al., 2015). On a global scale, or even national scale, the problem of urban mosaics is not as critical because urban land cover tends to be a low percentage of the total area. However, at smaller regional or watershed scales, urban land cover can be a significant percentage of the total. When total HANPP (above + below ground NPP) is calculated, root:shoot ratios are needed for forests, grasslands, and croplands and the root:shoot data are derived from the literature (e.g., Haberl et al., 2007).

Harvested Net Primary Production: $HANPP_{harv}$

$HANPP_{harv}$ is the amount of net primary production from row and fodder crops, timber, and grazing animals that are appropriated by humans (Haberl et al., 2014). Row crop and timber harvests are available at the national level from a variety of sources such as FAOstat. In the US, county level data for crop harvests are available for 5 years increments from the US Department of Agriculture. Assumptions need to be made for losses and residual crop carbon left behind (e.g., Haberl et al., 2007). Access to timber harvest data below the national level can be more problematic but is available for some regions (e.g., US Forest Service in the United States as used in Andersen et al. (2015)). Grazing harvest requires knowledge of the type and number of animals, amount of grazing land, and assumptions of the return flow of carbon to the soil via manure (see Haberl et al., 2007).

Net Primary Production Lost by Land Use Change: $HANPP_{luc}$

$HANPP_{luc}$ is the amount of net primary production appropriated by land transformation from one land use to another. The HANPP of land use change (luc), then, is the difference between the potential net primary production (NPP_{pot}) and the actual net primary production (NPP_{act}) of the landscape (Fig. 1). In nearly all cases, NPP_{act} is lower than NPP_{pot} . For example, converting forest cover with an above ground NPP of $1000 \text{ g C m}^{-2} \text{ yr}^{-1}$ to row crop with an above ground NPP of $500 \text{ g C m}^{-2} \text{ yr}^{-1}$ would be an above ground HANPP of 50% before harvest. The only exception to this rule would be where groundwater is used to convert desert into row crop, which results in an NPP greater than NPP_{pot} and an HANPP of greater than 100% (e.g., Haberl et al., 2007). Only a few locations at the global scale have HANPP greater than 100%, and all are in arid regions. Urban areas are the most extreme example of $HANPP_{luc}$ as impervious surface has an $HANPP_{luc}$ of 100% as NPP is effectively reduced to $0 \text{ g C m}^{-2} \text{ yr}^{-1}$.

Estimation of HANPP requires a number of assumptions (often unique to a given scale), extrapolation of datasets within and across different scales, and the use of computer models. As a consequence, there is always a level of uncertainty associated with each part of the HANPP calculation and the final estimations. Researchers interested in calculating HANPP for their region of interest should take the necessary time to consider these assumptions and the type of data available.

Global Patterns of HANPP

At the global scale, HANPP is calculated both in terms of mass of carbon per year (e.g., Pg C yr^{-1}) and as a percentage of the potential net primary production, NPP_{pot} . Global HANPP has been calculated using a number of methods over the years (see Haberl et al., 2014 for a history). Haberl et al. (2007) calculated that, for the year 2000, the global above ground HANPP was about 29% and global total HANPP was about 24%. This is significant in that the results indicate that nearly one third of the potential

global net primary production on an annual basis is appropriated by a single species—humans. Global mapping by Haberl et al. (2007) shows that HANPP is unequally distributed, with the highest appropriation percentages in India, eastern China, Europe, and the midwest of the United States (Fig. 2A), areas that classify as cropland and village anthromes. A few areas have high HANPP, such as southern Australia and western Africa but are smaller in spatial extent.

Similar to heterogeneity in spatial distribution, drivers of HANPP vary. Row crop harvest contributes nearly 50% of the global total HANPP, grazing on rangeland contributes nearly 29%, and timber harvest contributes almost 11% (Haberl et al., 2007). Thus, human food, fiber, and timber harvest account for 89% of the global total HANPP of $15.6 \text{ Pg C yr}^{-1}$. Not all HANPP_{harv} is used in a final form by humans, such as consumption of food (Krausmann et al., 2008). Indeed, about $\frac{2}{3}$ of HANPP_{harv} is used. The other $\frac{1}{3}$ of HANPP_{harv} is not used by humans, including crop residues and roots left behind or vegetation burned in fires.

Since 1900, global total HANPP has doubled to about 25% of potential net primary production (Krausmann et al., 2013). Compared to other indicators of global change this result is somewhat stunning given the exponential growth in the human population and consumption of resources, particularly post WWII (Steffen et al., 2011, 2015b; Krausmann et al., 2013). For comparison, affluence (measured as GDP) has increased over 20 fold and population has increased more than 3 fold during this time period (Steffen et al., 2011). This relative decoupling is a direct outcome of the agricultural intensification of the Green Revolution, as fertilizer, high-yield crop varieties, irrigation, mechanization, and pesticides have dramatically increased the yield of croplands (Foley et al., 2005, 2011). Thus, increasing yields associated with the Green Revolution dramatically slowed the expansion of cropland, even allowing reforestation in some parts of North American and Europe. The Green Revolution, particularly nitrogen fertilizer produced by the Haber-Bosch process, has allowed the population to grow far greater than the planet could otherwise support, but also led to a number of unintended consequences (Erismann et al., 2013). Although agricultural intensification reduced demand for arable land and thus limited the growth in HANPP, the trade-off associated with an exponential rise in nitrogen fertilizer use is an exponential rise in the greenhouse gas N_2O and a dramatic increase in hypoxic coastal zones (Steffen et al., 2015b). Additionally, much of the intensification of agriculture is driven by irrigation, which has led to falling groundwater tables around the world (Famiglietti, 2014).

The Potential Correlation of HANPP and Anthropogenic Biomes

Ellis and Ramankutty (2008), Ellis et al. (2010), and Ellis (2011) have developed the concept of anthropogenic biomes as a way to better show that the global ecological system is now essentially a human system that has semi-natural ecosystems embedded within it. In effect, they find that over 55% of the ice-free land surface is “used.” Used landscapes are those dominated by urban, village, row crop, and rangeland anthropogenic biomes. Urban land cover is relatively small ($\sim 3\%$) showing the primary importance of agriculture for land transformation. A comparison of the global distribution of anthromes (Fig. 2B) with that of global total HANPP (Fig. 2A) shows a distinct overlap of used anthromes with high total HANPP. Village anthromes in India and China, row crop anthromes in the midwestern United States, urban/row crop/village anthromes in Europe, cropland/rangeland anthromes in southeastern South America, and village/cropland anthromes in west Africa correlate with high HANPP. Perhaps the most striking example of all of these is India, with 60–100% HANPP and nearly 100% village anthrome. These patterns make sense, as anthromes are defined in part by population density (Ellis and Ramankutty, 2008) and population density has been found to have a strong correlation to HANPP (Krausmann et al., 2009). Additional research is required to fully understand the relationship, but on a broad scale, used anthromes with high land use intensity have the highest HANPP.

HANPP efficiency ($\text{HANPP}_{\text{harv}}/\text{HANPP}$) is typically highest in cropland anthromes associated with industrial agriculture (Haberl et al., 2014) or in village anthromes of Southeast Asia (Haberl et al., 2014) with high population densities. In contrast, regions with low HANPP efficiency are found in where there is low population densities. Additionally, areas with high HANPP_{luc} relative to HANPP_{harv} suffer from yield gaps. Yield gaps occur where NPP_{act} is well below the potential NPP for crops, often because of soil degradation or a lack of nutrients in cropland anthromes. Such areas would have low HANPP efficiency, such as sub-Saharan Africa (Haberl et al., 2014).

Local and Regional HANPP

Numerous studies have focused on HANPP at subglobal scales. Reviews of regional and national scale studies can be found in Haberl et al. (2014) and Andersen et al. (2015). These reviews show HANPP at the national level in the early 21st century ranged from about 20% to about 75% and is dominated by row crop and pasture. In summary, three main concepts emerge from these studies conducted at the national and regional scale. First, agriculture dominates estimates of HANPP at the regional and national scale. Second, HANPP exhibited considerable spatial heterogeneity. Third, even where trends emerge, such as declining HANPP, the trends include exceptions and show considerable temporal variability. These three concepts suggest local scale studies could increase our understanding of how human interaction with the landscape over time affects HANPP.

Studies conducted below the regional or national scale, such as the watershed scale, face multiple methodological hurdles. Largely, the problem is one of scaling datasets collected at one spatial and temporal scale to a spatial and temporal different scale. For example, Andersen et al. (2015) used county level data from the United States Department of Agriculture to calculate HANPP_{harv}. The method faced three significant challenges. First, they had to assume that the distribution of animals and crops at

Fig. 2 (A) Global map of the human appropriation of net primary production (HANPP) Data from Haberl et al. (2007). (B) Global map of anthropogenic biomes. Data from Ellis et al. (2010) Insets highlight similar patterns in three locations between HANPP and anthrome type.

the county scale held for the watershed scale. Second, the USDA farm level data is only collected every 5 years, and the agricultural data was collected in 1969 and 2007, which didn't match the aerial photos (1968) or satellite data (2011) year. This leads to uncertainties in the analyses, but probably less than the difference between the 2 years. Third they had to digitize aerial photos to have comparable spatial data for land use and land cover and for sufficient accuracy for the analysis. This is similar to the challenges faced by Krausmann et al. (2013) when attempting to calculate global HANPP back to 1900.

Embodied HANPP

Calculation of HANPP national, regional, state, and local scales needs to consider how energy flows are impacted by or impact other near or distant regions. The material footprint of humanity has expanded dramatically with the great acceleration, tripling since 1970 (Wiedmann et al., 2013). The material footprint, of which biomass is a part, provides a measure of the consumption of resources by nations and accounts for both domestic use and imported/exported material associated with global trade. The concept of embodied HANPP (Erb et al., 2009) is similar to the biomass part of the material footprint. Embodied HANPP, or eHANPP, demonstrates the pressure exerted on ecosystems associated with the imports and exports of biomass, thereby connecting regions that are net producers (exporters) of biomass to net consumers (importers) of biomass (Haberl et al., 2009, 2014). Erb et al. (2009) completed a detailed analysis of embodied HANPP on a global scale. Not surprisingly, urban regions had the highest eHANPP consumption. Thus, eHANPP shows a transfer from rural (cropland and village) anthromes to urban anthromes. The eHANPP also represents the impact of globalization, with trade of eHANPP between countries. However, relatively few countries as of 2000 were involved in this imbalance (Erb et al., 2009; Haberl et al., 2014). Only 10 countries, mainly in the Americas and Oceania, were major net exporters and only 10 countries, mainly in East Asia and Europe were major net importers. Trade of eHANPP could certainly increase as population grows and as the affluence of less developed countries increases.

Critiques of the HANPP Method

The HANPP method is, above all, a model. As with any other model, HANPP relies on a variety of assumptions and simplifications of the real world. For example, the NPP_{pot} of a given watershed, nation, or region is a model based on local empirical data that subsequent extrapolation relies on assumptions of how plants might grow in response to heterogeneous climate and soil conditions. Perhaps the most thorough critique of the HANPP method is in Smil (2011). Smil's primary critique was that many of the variables are poorly quantified and have large margins of error, largely because the numbers are from national scale datasets that have to be extrapolated to smaller scales. Additionally, the model is based on land use classification at the $5' \times 5'$ scale, which can be difficult to resolve because of landscape heterogeneity. Reflective of the maturation of the concept, many of the issues brought up by Smil (2011) have been addressed by Running (2012) and Haberl et al. (2014), among others.

Perhaps the most important critique is that HANPP does not consider the *qualities* of the affected land area. For example, converting the current rainforest to cattle pasture or soy production today is far more damaging to biodiversity and ecosystem function at this moment than rice production in Southeast Asia that may have been cultivated for centuries (Smil, 2011). HANPP also is *lowered* by intensifying agriculture, so there is the trade-off of lower HANPP for higher environmental impact beyond a given region, as noted above. Although the latter are valid critiques, HANPP remains a valuable measure of the human impact on the landscape caused by land use change and biomass harvest and aligns well with anthropogenic biomes.

Summary

HANPP is a model that estimates how much net primary production humans appropriate, or co-opt (Running, 2012), by land use change, harvest, and fire (Haberl et al., 2007). The model may have a relatively high uncertainty and not account for the environmental trade-offs of intensive agriculture which lowers HANPP. However, the global scale results suggest that humans are appropriating approximately one-third of aboveground net primary production and one-quarter of total (above + below ground) NPP (Haberl et al., 2007, 2014; Krausmann et al., 2013), suggesting HANPP is a clear quantitative measure of global change. In addition, and valuably for global synthesis, global HANPP patterns correlate well with anthropogenic biomes, suggesting that HANPP is an important and scalable measure of human impact on the terrestrial environment.

Abstract

Biodiversity conservation is traditionally presented in the context of biomes and ecoregions. However, these frameworks fail to incorporate the extent to which humans have shaped ecosystems on local and global scales and may provide an inaccurate representation of ecological associations in many landscapes. In this article, we review global biodiversity within the context of anthromes; a global classification of land use and land cover patterns that reflects population density and land use intensity. We review species richness data for birds, mammals, and amphibians as a factor of anthrome classification and compare our results with existing plant richness data. Plant, bird, mammal, and amphibian richness is greater in anthromes with higher population density and moderate land use intensity. Village and rangeland anthromes are frequently the most species rich. Richness of threatened species is also highest in village anthromes. There is a positive correlation between total richness and threatened species richness for birds and mammals, but not for amphibians. These data suggest that conservation programs can and should work to prioritize conservation in ecosystems with higher population density and land use change. Future work should consider different biogeographical extents to improve understanding of biodiversity patterns in anthromes.

Introduction

Spatial patterns of global biodiversity, prioritization, and protection are most often associated with biomes and ecoregions, which are ecological classifications reflecting temperature, precipitation, elevation, and latitude. Studies of biodiversity and conservation through this traditional lens have revealed global patterns and changes in biodiversity. For example, [Tedesco et al. \(2014\)](#) examined fungal diversity by biome and biogeographic region and [Pimm et al. \(2014\)](#) ranked richness of plants and fish by ecoregion and analyzed distributions of mammals, birds, and amphibians. [Chape et al. \(2005\)](#) reviewed the number, extent, and effectiveness of current global protected areas in relation to biomes; [Hoekstra et al. \(2005\)](#) mapped protection and habitat loss, ranking rates of change by biome and ecoregion; and [Joppa and Pfaff \(2009\)](#) mapped protected area by ecoregion and assessed the effectiveness of their placement. Biome and ecoregion frameworks have also been used to model and anticipate future changes; for example, [Sala et al. \(2000\)](#) provided a ranking of biomes with respect to expected ecosystem changes across varying scenarios for the year 2100.

Given the extent of human influence on the landscape, global narratives based strictly on biotic and abiotic factors may not provide the most realistic representation of biodiversity distributions and change ([Martin et al., 2014](#)). Agricultural lands, including cropland and rangeland, cities, and peri-urban landscapes, continue to expand in scale and impact. Land for the production of food, fiber, and fuels encompasses at least 39% of Earth's ice-free surface ([Foley et al., 2005](#)), and while cities only cover approximately three percent of the world's surface area, their impact extends far beyond municipal boundaries (e.g., [Brown and Quinn, 2018](#)). It is understood that land use and land cover change shifts species diversity patterns, but the extent, impact, and permanence of these anthropogenic land use and land cover types necessitates research to understand how biodiversity varies within and between anthropogenic ecosystems like farms, cities, and villages.

Anthromes (anthropogenic biomes) build on the existing biome classification system and incorporate land use intensity and human population density ([Ellis et al., 2010](#)) to reflect the extent to which humans have shaped the Earth's surface. With now over 55% of the terrestrial biosphere being anthropogenic and less than 45% remaining wild or seminatural, it is crucial to integrate human influence into the framework with which we consider biodiversity and conservation ([Ellis et al., 2010](#)). [Ellis et al. \(2012\)](#) applied the anthrome framework at a global extent to map plant diversity and found that plant richness was greatest in seminatural remote woodlands (Fig. 1; Anthrome 53), dense mixed settlements (Anthrome 12), and pastoral villages (Anthrome 24) and lowest in wild woodlands (Anthrome 61), seminatural inhabited treeless and barren lands (Anthrome 54), and wild treeless and barren lands (Anthrome 62). Anthromes have also been used to frame biodiversity patterns at local extents for birds (e.g., [Quinn et al., 2014](#); [Quinn et al., 2017](#)) and for mammals ([Gómez et al., 2018](#)), but vertebrate biodiversity has not yet been analyzed by anthrome at a global scale. Building on both biome and anthrome-focused studies, and considering how vertebrate species may differ in their distributions within and across anthromes, we review global spatial patterns of vertebrate richness (birds, mammals, and amphibians) as a function of anthrome type.

For this review we obtained global anthrome classification and distribution data for the year 2000 from the Anthromes version 2.0 ESRI Binary Grid ([Ellis et al., 2010](#)). We obtained species richness data for birds, mammals, and amphibians from

Fig. 1 Patterns of median plant richness across anthromes. Data from Ellis EC, Antill EC, and Kreft H (2012) All is not lost: Plant biodiversity in the anthropocene. *PLoS One* 7(1): e30535. <https://doi.org/10.1371/journal.pone.0030535>.

BiodiversityMapping.org (Jenkins et al., 2013; Pimm et al., 2014) that incorporates breeding bird ranges from BirdLife International and range data for mammals and amphibians from the International Union for the Conservation of Nature (IUCN). Threatened species classifications were determined by Jenkins et al. (2013) and Pimm et al. (2014) based on species considered vulnerable, endangered, or critically-endangered on the IUCN Red List. The above data were created at a global extent with input data from IUCN, BirdLife International, NatureServe, and USGS.

We re-projected the species richness data to align with the projection of anthrome data using ArcMap version 10.5.1 (ESRI) and rescaled it using the resample tool in ArcGIS to match the cell size of the anthrome data (5 arc-minute grid cell (km^{-2})). Using raster calculator, we created a new raster containing anthrome classification and species richness within each cell. This produced count data indicating the number of cells of a particular anthrome classification with particular species richness (0 through n). We calculated richness by anthrome at a global extent. We used the package “splitstackshape” (Mahto, 2018) to expand the data obtained from ArcGIS. We created plots using the “ggplot2” package (Wickham, 2016). Subsequent correlations (significance set to an alpha value of 0.05) and all data processing were done using R version 3.4.3.

Results and Discussion

Among all bird species (Table 1 and Fig. 2), median richness is the highest in rice villages ($n = 289$), followed by residential rangelands (275), pastoral villages (267) and residential woodlands (256). The total median richness is lowest in wild (38) and seminatural (93) barren lands. The median number of threatened birds is the greatest in villages. The median richness for threatened bird species is highest in rice villages (9), irrigated villages (6), rainfed villages (6), and pastoral villages (6). The lowest median richness for threatened birds is in wildlands (1), barren lands (1), and remote rangelands (1). There is a strong positive correlation ($r = 0.781$, $p\text{-value} = 0.000$) between median richness of total and threatened bird species (Fig. 3). There is also a strong positive correlation ($r = 0.749$, $p\text{-value} = 0.0002$) between mean richness of total and threatened species (Fig. 3B).

The median richness of all mammals (Table 1 and Fig. 2) is highest in pastoral villages ($n = 74$), residential rangelands (72), and residential woodlands (66). Total mammal richness is lowest in wild (15) and seminatural (28) barren lands, wild woodlands (33), and remote rangelands (33). The greatest richness of threatened mammals is in seminatural remote woodlands (6) followed by rice villages (5). Richness for threatened mammals is relatively low across all anthromes (min = 1, max = 6), however richness was lowest in barren lands (1), wildlands (1), residential (2) and remote (2) rangelands, all cropland anthromes (2), and dense urban (2) and mixed (2) settlements. There is a positive correlation ($r = 0.510$, $p\text{-value} = 0.026$) between median richness of total and threatened mammal species (Fig. 3) and a strong positive correlation ($r = 0.787$, $p\text{-value} = 0.0000$) between mean richness of total and threatened mammal species (Fig. 3B).

The median value of total species richness of amphibians (Table 1 and Fig. 2) is highest in residential woodlands (18), rice villages (17), residential rangelands (16), pastoral villages (16), and mixed settlements (16). The lowest richness is in wild barren lands (1), wild woodlands (2), and seminatural barren lands (3). Median species richness of threatened amphibians is low across all anthromes (min = 1, max = 2), but highest amongst rainfed (2) and pastoral (2) villages. There is no correlation between median total and threatened richness ($r = 0.244$, $p\text{-value} = 0.314$; Fig. 3) or between mean total and threatened richness ($r = 0.299$, $p\text{-value} = 0.213$; Fig. 3B).

Fig. 2 Median total richness and threatened richness of birds, mammals, and amphibians by anthrome type. Richness data from Jenkins CN, Pimm SL, and Joppa LN (2013) Global patterns of terrestrial vertebrate diversity and conservation. *PNAS* 110(28): E2602–E2610; Pimm SL, Jenkins CN, and Abell R (2014) The biodiversity of species and their rates of extinction, distribution, and protection. *Science* 344(6187): 1246752.

The results show high variation in vertebrate species richness by anthrome, low species richness in barren and wildlands, and higher richness in villages and rangelands. These results are consistent with the findings of the Ellis et al. (2012) analysis of plant richness. Upon further analysis of the distribution of vertebrate richness by anthrome, several significant patterns emerged. Village anthromes exhibit high median total richness and threatened richness, specifically among rice and pastoral villages. This pattern may be a result of the distribution of village anthromes in tropical systems where historical biodiversity patterns were shaped by temperature and precipitation that resulted in higher potential species richness. High threatened species richness in villages is consistent with high rates of decline of biodiversity in tropical regions and rapid land use change. Residential rangelands and seminatural residential woodlands also have high total richness across taxa, while remote rangelands have among the lowest richness of threatened birds and mammals. The low threatened species richness in rangelands may be attributable to effective and sustainable management resulting from a history of multifunctional land use (e.g., Havstad et al., 2007) where grazing and conservation have gone hand in hand. Richness, both total and threatened, is consistently low among wild treeless and barren lands, seminatural inhabited treeless and barren lands, and remote rangelands. These patterns of low richness despite low human interference is likely a consequence of broader biogeographical and evolutionary patterns that make these regions less hospitable to wildlife.

Overlap in anthromes of high richness between taxa presents opportunities for conservation. Three anthromes (pastoral villages, residential rangelands, and residential woodlands) have among the highest richness for both birds and mammals. Although the anthrome with the highest total bird richness (rice villages) was not among the highest richness for mammals, the overlap between the two taxa reveals an opportunity for prioritization of conservation efforts across multiple taxa. This also suggests that anthrome classifications could be used to target specific anthrome types for conservation efforts. Beyond these three anthromes, the correlations between total and threatened richness for birds and mammals presents an opportunity for conservation action both broadly and for targeted species to be complementary. The correlation between median total and threatened richness was not as strong for mammals as it was for birds though the correlation values of the means were similar. Both associations are positive, again suggesting complementary efforts are possible. Moving forward, there is a need to analyze richness by anthrome type at varying spatial extents to more fully understand these patterns of richness, both within and between anthromes, and their implications.

Conclusion

This work builds on a deep foundation of research focused on biomes and ecoregions. However, by considering spatial biodiversity patterns as a function of anthromes, we can begin to understand and create conservation solutions that integrate human and natural systems. This shift in global frameworks offers new opportunities for improvement in conservation research and implementation. While most conservation research has focused on lands classified as “natural,” despite the extent and permanence of human land use types (e.g., urban, cropland, rangeland), this review highlights the value of focusing research and prioritization on inhabited and seminatural lands. The global patterns of species richness described in this review can help identify and prioritize conservation efforts beyond wildlands and protected areas. This focus on anthromes does not suggest that natural or protected areas are unimportant, rather it emphasizes the need to consider lands beyond the boundaries of protected areas which are often deprioritized or overlooked in the broader context of conservation prioritization. This review reveals a clear overlap in anthromes of high

Fig. 3 (A) Correlation between median total richness and threatened richness of birds, mammals, and amphibians for each anthrome type. (B) Correlation between mean total richness and threatened richness of birds, mammals, and amphibians for each anthrome type. population density, moderate land use intensity, and high richness across multiple taxonomic groups. This overlap, along with the positive correlation between threatened and total species for birds and mammals, indicates a significant opportunity for congruent conservation action across anthromes. Further spatial analyses at varying biogeographical extents are needed for a deeper understanding of species distribution within the anthrome framework.

Abstract

The world’s population has gone from 30% urban in 1950 to 55% urban in 2018, and will be 60% urban by 2030 (United Nations Population Division, 2019b). Urban areas are the most intensely and densely settled places human inhabit on the planet. Though they comprise less than 3% of Earth’s land surface area, they account for an estimated 78% of global carbon emissions, 60% of residential freshwater use, and 76% of wood use (Grimm et al., 2008). In this article, we discuss the concepts crucial to understanding urban social-ecological systems, including articulating some of the dialogue around defining some key terms, comparing frameworks used to research urban systems, and briefly discuss the related discipline of urban ecology.

Urban Social-Ecological Systems

The extent of human impact on the planet is such that several scholars have articulated the need for alternative conceptualizations of the classic human-nature dichotomy. For instance, Ellis and Ramankutty (2008) proposed the concept of “anthropogenic biomes” or “anthromes” to capture the global impact of humans on all ecosystems. Meanwhile, geologists (e.g., Zalasiewicz et al., 2015; Waters et al., 2016) and sustainability scientists (Steffen et al., 2015) have argued that the current widespread human alteration of Earth system processes warrants designating an entirely new geologic period the “Anthropocene.” Increasingly, humans and nature cannot be separated, no matter where you are on the planet. Urban areas, as home to a majority of the world’s population (United Nations Population Division, 2019a), are arguably front and center in this new world. Though urban areas comprise less than 3% of Earth’s land surface area, they account for an estimated 78% of global carbon emissions, 60% of residential freshwater use, and 76% of wood use (Grimm et al., 2008). Thus, it is crucial to understand the social and ecological mechanisms driving the structure and dynamics within urban areas, as well as how urban areas impact surrounding ecosystems and global Earth systems processes.

Urban areas are the most intensely and densely settled places human inhabit on the planet. They have extensive so-called “gray infrastructure” above and below ground (often called the “built environment”). Urban areas have more “natural” elements like trees and parks (often called “green infrastructure”), as well as natural or constructed bodies of water (called “blue infrastructure”; Table 1 and Fig. 1). The infrastructures of cities are cohabitated not just by people, but also by wildlife, both more desirable (e.g., birds, butterflies, sometimes rabbits and squirrels) and less desirable (e.g., rats, raccoons, monkeys, coyotes, any number of insect pests such as cockroaches, fire ants; cf., Nyhus, 2016) from a human standpoint, and any number of relatively invisible types of biodiversity such as insects and microbes that live in the soil, trees, yards/gardens, greenroofs, and every corner of the built environment. Beyond the physical and ecological elements of urban areas, there are innumerable social elements: politics and political systems; formal and informal economic activities; social norms of appropriate behaviors; demographic patterns related to living, working, and moving about the city; concerns about inequality, inequity, and participation in city life; and numerous other issues connected to housing, education, crime and violence, jobs and employment, transportation, etc. Furthermore, these social issues have significant impact on the quality of and access to gray, green, and blue infrastructure (cf., Taylor, 2009).

In this article, we discuss the concepts crucial to understanding urban social-ecological systems, including articulating some of the dialogue around defining some key terms, comparing frameworks used to research urban systems, and briefly discuss the related discipline of urban ecology.

Table 1 The biophysical elements of urban social-ecological systems include all types of gray, green, and blue infrastructures, some of which are listed below, as well as the living things—human and non-human—inhabiting these infrastructures.

<i>Gray infrastructure</i>	<i>Green infrastructure</i>	<i>Blue infrastructure</i>
Water management systems: Sanitary sewers and septic tank systems, potable water delivery systems, stormwater drains and pipes and underwater storage tanks, seawalls, levees, etc.	Trees (in parks, along streets, sidewalks, alleys, on vacant lots, adjacent to railroad or light rail tracks, in yards, in parking lots, etc.)	Natural or remnant bodies of water: Lakes, rivers, streams, bays, wetlands
Electrical power and cable/internet lines	Public and private gardens and yards	Constructed bodies of water: Canals, reservoirs, retention ponds for stormwater runoff, harbors and marinas
Energy infrastructure: Conventional power plants (coal, natural gas, nuclear, etc.), Solar panels, etc.	Parks, large and small	
Paved impervious surfaces: Roads and highways, plazas, sidewalks and walking paths, parking lots, driveways, piers	Nature preserves or reserves (remnants of the surrounding native ecosystem such as forest or prairie, or of a constructed or restored type, e.g., a constructed wetland)	
Transportation infrastructure: Bridges, tunnels, street car tracks, light rail and elevated train tracks, subway systems, gondola lifts	Sports and recreation fields (<i>when covered in living grass as turf rather than astro-turf</i>): Golf courses, baseball diamonds, football fields, etc.	
Buildings, large and small, ranging from the smallest, stand-alone houses, sheds, and garages, to extensive conference or hotel centers occupying land equivalent to several city blocks, to tall skyscrapers with dozens of stories above ground and sometimes several basements and subbasements below	Cemeteries	
	Green areas at institutions, like school campuses, hospitals, business or industrial parks	
	Other landscaped areas, sometimes called “greenspaces”	

Key Definitions

In order to understand urban social-ecological systems as an anthropogenic biome, we need to unpack the concept of “social-ecological system” and the meaning of “urban.”

What Is a “Social-Ecological System”?

Social-ecological systems (SESs) are those where there are both human and natural components interacting to produce observed system-level outcomes. [Colding and Barthel \(2019\)](#) review the discourse on SESs over the past several decades. They note that the term “social-ecological system” was first defined in 1988 in the context of epidemiology by Cherkasskii, who spoke of the “biological” and “social and economic conditions” as “two interacting subsystems” where the social subsystem “acts as the internal regulator” of the biological subsystem processes and mediates interactions between the social and biological (1988; as quoted in [Colding and Barthel, 2019](#)). In the context of human impacts on ecosystems, the term was expanded upon in 1998 by [Folke and Berkes \(1998\)](#), who viewed the social-ecological system as a complex, dynamic, open system whose properties are influenced by the surrounding ecological and social systems. [Folke and Berkes \(1998\)](#) also developed the first framework for SESs, which posited a language and analytical structure for examining natural resource systems and the fit of management institutions (rules, strategies) with ecological dynamics. Subsequently and in-part based on the [Folke and Berkes \(1998\)](#) work, [Ostrom \(2007, 2009\)](#) also proposed a SES framework for examining the sustainability of natural resource use in common property settings. Ostrom’s SES framework—called the “most comprehensive conceptual framework for diagnosing interactions and outcomes” in SESs ([Partelow, 2018](#)) (Ostrom won the Nobel Prize in Economics in 2009)—comprises nested sets of variables related to the social components (governance system, users of the resource) and biophysical components (properties of the resource system, i.e., a forest, and individual resource units, i.e., trees or other forest products) of the system interacting with one another to produce outcomes ([Partelow, 2018](#)). (For more on frameworks in the context of urban systems, see the section below on “Frameworks for Understanding Urban SESs.”)

The origins of the SES concept as described above are in rural natural resource management systems where there is some type of resource being harvested or used by the managing community—e.g., forests being managed for timber, fisheries for fishing, irrigation systems for watering crops. Resource use happens differently in urban areas. For example, timber products needed for building are not (usually) harvested from within a city, but rather brought in from outside forests, while the resources generated by cities are things like the ecosystem services provided by green infrastructure ([Jerome et al., 2019](#)), innovation ([Florida, 2011](#)), economic activities ([Pain et al., 2016](#)), or even human social capital or community connections (e.g., [Sampson and Graif, 2009](#)). Nonetheless, cities are perhaps the most quintessential SESs. In urban areas, the “social” part of SESs is arguably most dominant to the average urban dweller. Social elements include all those constructs of human society, ranging from the often-intangible social and political dynamics of urban dwellers (working, shopping, going to school, engaging in community and leisure activities like going to religious services, volunteering, recreating, socializing, etc.) to the more tangible impacts resulting from the way people move about and act on urban areas (through, for example, walking, driving cars, planting and maintaining trees and landscaping, growing food or flowers, constructing roads and buildings, and even littering). The “ecological” part of urban SESs is perhaps better

Fig. 1 Examples of gray, green, and blue infrastructure in urban social-ecological systems described in Table 1 from the authors' home city of Chicago, IL (A–D), Venice, Italy (E), and Shenyang, China (F). (A) Buildings, roads, sidewalks and other gray infrastructure in Chicago's downtown. (B) A restored riparian area (in the foreground) along the South Branch of the Chicago River (blue infrastructure) in Ping Tom Memorial Park (green infrastructure) in Chinatown on Chicago's south side. (C) The entrance to Diversey Harbor on Lake Michigan (blue infrastructure) on Chicago's north side with the downtown skyline visible in the background. (D) Tree tops and buildings (green and gray infrastructure, respectively) in Chicago's Lincoln Park neighborhood with Lake Michigan (blue infrastructure) visible in the background. (E) Perhaps one of the best known constructed blue infrastructures is the network of canals in Venice, Italy. (F) A man fishes along a waterway (blue infrastructure) adjacent to a park in Shenyang, China. Residential buildings of identical height (gray infrastructure) are visible in the skyline in the background. All photos by author J. Vogt.

conceptualized as “biophysical,” that is, all of the biological/ecological and physical elements in the city, inclusive of the built environment and green and blue infrastructures described in Table 1.

What Is “Urban”?

An understanding of what is “urban” means is crucial for a complete understanding of urban SESs. Generally, there are three ways of defining urban relevant to studying urban areas: by population size or density, by physical or ecological features (geographic definition), by jurisdiction or administrative unit (governance definition). Each of these three are described below, as well as their implications for understanding urban SESs.

Population-based definitions of urban

Technically, “urban” is defined by each individual country or region, but most countries use as at least part of their definition the total number of people or the density of people living in a contiguously developed area (UN Population Division, 2019a). For example, in the United States, “urbanized areas” refer to those with more than 50,000 people (U.S. Census Bureau, 2018). A related term, “urban clusters,” refers to areas with 2500–50,000 people, and “rural” encapsulates all non-urban areas (U.S. Census Bureau, 2018). The Canadian definition of urban includes slightly smaller communities, defined as population centers of more than 1000 people, but also adds a population density threshold of more than 400 people per square kilometer (Statistics Canada, 2017). Across the world, localities or towns with 2000 or more people appears to be a common threshold population size that makes an area classified urban, though the most recent edition of the United Nations’ *World Urbanization Prospects* report notes that this threshold varies widely from 200 to 50,000 people (United Nations Population Division, 2019a). In Africa, areas defined as urban vary from a minimum size of 2000 people (in Ethiopia, Kenya) to 5000 (Zambia) to 10,000 (Senegal) (Francis and Chadwick, 2013, after United Nations Statistics Division, 2017).

Because of this variability, the European Commission has undertaken an effort to standardize the definitions for urban in order to more consistently track urbanization. The European Commission considers an “urban center” to be an area with “a minimum of 50,000 inhabitants *plus* a population density of at least 1,500 people per square kilometer (km²) or density of build-up area greater than 50 percent” and an “urban cluster” to be an area with “a minimum of 5,000 inhabitants *plus* a population density of at least 300 people per square kilometer (km²)” (Ritchie, 2018, *emphasis in original*). The total population and population density of an urban area are not related; that is, larger cities are not necessarily denser (Fig. 2).

Using the UN’s country-defined concept of “urban,” 55% of the global population lives in urban areas as of 2018 (United Nations Population Division, 2019a). Using the European Commission’s standardized definition, 85% of the global population lives in urban areas (52% in urban centers and another 33% in urban clusters) as of 2015 (Ritchie, 2018).

Biophysical definitions of urban

Beyond defining urban areas based on population, there are definitions based on physical or ecological aspects of urban areas that use geographical data. Although most country-specific definitions of urban utilize population or population density as summarized above, occasionally they will use a more biophysical definition. Algeria, for example, uses how many “constructions” (presumably, buildings) are in a geographical area, and there must be 100 or more constructions spaced 200 m or less apart for an “urban” area (United Nations Statistics Division, 2017, as quoted in Francis and Chadwick, 2013).

Researchers interested in determining how much land area on Earth is “urban” are most concerned with physical and ecological definitions of the term. For instance, Schneider et al. (2009), in their analysis of global urban extent based on remote sensing data, eschew population-based definitions entirely and use a spatial definition that,

...define urban area based on the physical attributes and composition of the Earth’s land cover: urban areas are places dominated by the built environment. The “built environment” includes all non-vegetative, human-constructed elements, such as roads, buildings, runways, etc. (i.e., human-made surfaces), and “dominated” implies coverage greater than 50% of a given landscape unit (the pixel). (Schneider et al., 2009, p. 2)

Using this definition, Schneider et al. (2009) report that only 0.5% of Earth’s land surface area is urban. This is one of the smallest reported percentages in the literature. Their definition of urban is crucial to understanding why. Because these authors are conducting a pixel-by-pixel analysis of urban area using data at 500-m spatial resolution, they must decide what to do with pixels that are not majority “built environment” per the definition above, but may still be located within the conventional boundaries of a city. Schneider et al. (2009) continue, “When vegetation (e.g., a park) dominates a pixel, these areas are not considered urban, even though in terms of land use, they may function as urban space” (p. 2–3). They further clarify that “urban areas are contiguous patches of built-up land greater than 1 km²” (Schneider et al. (2009), p. 3). Other geographical analyses of urban land area extent using satellite-based data have estimated as low as 0.2% urban area and as high as 2.4% as of 2000 satellite data (Potere and Schneider, 2007). The higher of these estimates is data from the Global Rural-Urban Mapping Project (GRUMP), which is the source of the oft-cited statistic that urban areas comprise “<3%” of global land area (e.g., Grimm et al., 2008).

Urban extent analyses based on ecological character might define urban areas very differently. For instance, Ellis and Ramankutty (2008) in their classification of global land area into levels anthropogenic biomes (“anthromes”) use population density in combination with land use and land cover data to define two relevant classes of highly-settled biomes. “Dense settlements” are defined as those “with substantial urban area” inclusive of “urban” (“dense built environments with very high populations”) and

Fig. 2 Population density by total population for the 100 largest cities (by total population). Data sources: *Population density data* downloaded from: Our World in Data (2014) “Population Density by City, 2014.” Available from: <https://ourworldindata.org/grapher/population-density-by-city> (Accessed 13 Dec 2019). Originally from: United Nations, Department of Economic and Social Affairs, Population Division (2014) *World Urbanization Prospects: The 2014 Revision*, CD-ROM Edition. <http://urbandata.unhabitat.org/>; *Total population data* downloaded from: United Nations, Department of Economic and Social Affairs, Population Dynamics (2018) *World Urbanization Prospects 2018, File 12: Population of Urban Agglomerations with 300,000 Inhabitants or More in 2018, by country, 1950–2035 (Thousands)*. Available from: <https://population.un.org/wup/Download/> (Accessed 13 Dec 2019).

“dense settlements” (“dense mix of rural and urban populations, including both suburbs and villages”) biomes (Ellis and Ramankutty (2008), p. 442). The “villages” biome is “dense agricultural settlements” inclusive of several different types of agricultural village biomes (e.g., rice villages, pastoral villages; Ellis and Ramankutty (2008)). According to these definitions, Ellis and Ramankutty (2008) classify 1.1% and 5.9% of ice-free land area in “dense settlement” and “village” anthromes respectively, and state that 80% of the total global population lives in these densely settled area. However, because of the composite use of population density, land use, and land cover data with which the anthromes are specified, not all land use with these densely settled anthromes is urban: 57% of land use within the dense settlements biome is urban, while 35% of villages biome land use is urban (WebTable 2 in Ellis and Ramankutty, 2008).

Governance-based definitions

From an urban governance perspective, there are three additional terms relevant to a discussion of what is urban from an urban SES point of view and used by the United Nations and others in defining, describing, and studying cities. The first is “city proper,” which refers to the administrative or jurisdictional boundary of a municipality (i.e., a city, town, village, etc.; United Nations Population Division, 2019b). This definition is in contrast to that of “metropolitan area,” which includes a larger geography around the city proper “according to the degree of economic and social interconnectedness of nearby areas” (United Nations Population Division, 2019b). The final, perhaps most meaningful for urban SESs, is “urban agglomeration,” which is defined as

...the population contained within the contours of a contiguous territory inhabited at urban density levels without regard to administrative boundaries. It usually incorporates the population in a city or town plus that in the suburban areas lying outside of, but being adjacent to, the city boundaries (United Nations Population Division, 2019c).

These terms are important from the perspective of urban social-ecological dynamics: What a city itself considers its jurisdictional or functional boundary impacts land use, land cover, and other ecological and social patterns and processes. For instance, commuters coming by car, bus, or train into the city creates a social and economic connection between the city proper and the surrounding metropolitan area or urban agglomeration, but also has an ecological impact in terms of the carbon emissions and land cover of different forms of transportation.

Clearly, the definition of urban is complicated at best. For a SESs view of “urban,” total population size, population density, built-up area, ecological characteristics, and governance/administrative boundaries all impact the social-ecological nature of a city. Fig. 3 describes some of the social and ecological considerations for cities with different total populations and population densities.

It is an open question which type of definition of “urban” is most useful from an urban SES perspective. Within the field of urban ecology, there is a debate on what constitutes “urban” for the sake of research. MacGregor-Fors (2011) in a classic article from the urban ecology field entitled, “Misconceptions or misunderstandings? On the standardization of basic terms and definitions in urban ecology,” argues that the lack of standard definitions obfuscates the ability of urban ecological research to be fully comparable across studies. He further encourages urban scholars to specify the following seven pieces of information for their study:

(1) the geographical location of the study area in lat/long format to facilitate comparisons (reporting the location of the geographical center of the urban study site), (2) total number of inhabitants at the time when the study was conducted, (3) updated human population growth rate (in a percentage scale to allow comparisons), (4) size of the urban area (in square kilometers. . .), (5) main urban land uses (even though the study may not explore them), (6) the biogeographic (e.g., zoogeographic, phytogeographic) region in which the urban area is settled, (7) type of habitats present prior to the establishment of the urban area, and (8) principle habitats and land uses currently surrounding the urban area (MacGregor-Fors, 2011: p. 348).

This approach would certainly help with consistency and allow for better comparison across studies of urban systems of different types and sizes and across multiple locations, climates, etc.

Urbanization

Regardless of how urban areas are defined—whether by population size or density, by built-up area, or by biome—throughout the history of human civilization, urbanization has increased. Urbanization is the process through which people and geographies become more urban—that is, more built-up, more densely settled, of larger geographic dimensions, etc. (United Nations Population Division, 2019a). By the UN’s country-specified definitions, the world’s population has gone from 30% urban in 1950 (United Nations Population Division, 2019a), to 55% urban in 2018, and will be 60% urban by 2030 (United Nations Population Division, 2019b). In 2018, one in eight urban residents lives in megacities of more than 10 million people, 23% live in cities of 1 million or more, and half of the global urban population lives in cities of less than 500,000 people (United Nations Population Division, 2019b). By 2030, 706 cities of more than 1 million will house 28% of the global population (United Nations Population Division, 2019b). According to Seto et al. (2011)’s geographic analysis of urbanization, by 2030 global urban land extent will be nearly three times what it was in 2000, with 1.2 million km² of new urban land. In their words, “the first 30 [years] of the 21st century is highly likely to experience more urban land expansion than all of history” (Seto et al., 2011; p.16088). Together, these analyses indicate that while the urban population will increase by only 22% (from 4.2 billion to 5.2 billion; United Nations Population Division, 2019b), these people will be occupying three times the land area occupied by cities at present (Seto et al., 2011).

Urbanization will have significant negative impacts on global ecosystems (cf., Johnson, 2013). Seto et al. (2012) projected that future urban expansion (to three times current urban extent) will result in substantial biodiversity loss, particularly in regions of the world that were relatively unimpacted by urbanization prior to 2000 such as the biodiversity hotspots in the mountains of eastern Africa, the Western Ghats (a mountain range on the southern Indian peninsula), and Sri Lanka. Carbon emissions due to urbanization will also be substantial: “loss of vegetation biomass. . . [will be] equal to ~5% of emissions from tropical deforestation and land-use change” (Seto et al., 2012).

Clearly, urbanization is not occurring equally in all regions of the planet. China, for instance, is urbanizing rapidly, from 18% in 1978 to 55% in 2014 (Huang et al., 2016). Annual regional urbanization rates—that is, the rate of increase in urban populations—for the period from 1995 to 2015 range from 3.44% to 2.78% in Africa and Asia respectively to just 0.31% in Europe and 1.24% in North America (UN-Habitat, 2016).

Frameworks for Understanding Urban SESs

Given that both urban areas (Seto et al., 2011) and the number of people living in them (United Nations Population Division, 2019a) will continue to steadily increase through the first half of the 21st century, and that urban areas constitute the vast majority of global demand for natural resources (water, materials, energy, etc.; Grimm et al., 2008), understanding the social and ecological patterns and processes at work in cities is crucial to creating cities that are livable and sustainable. Urban SESs are complex, dynamic systems with both human and natural components.

One of the more useful ways of studying and describing SESs is through the use of a framework, or a structured set of variables organized in a way that describes the potential interactions among them. Ostrom (2010), in the version of her 2009 Nobel Prize in Economics speech printed in the *American Economic Review*, expounded on the utility of frameworks for research:

Type	Description		Select social & ecological considerations
Dense megacities <i>HIGH total population, HIGH population density</i>	Urban agglomerations of more than 10 million people are often called 'megacities' (United Nations Population Division 2019b). In addition, megacities are geographically large and often quite dense. There were 29 megacities as of 2015 (Figure 1), 33 in 2018, and will be 43 megacities by 2030 (<i>ibid.</i>). But not all of these are densely populated: The Tokyo metropolitan area, for instance, comprises more than 37 million people, yet hosts only 4,400 people per square kilometer. Population densities of more than 5,400 people per kilometer mile earn a city a place on the list of the top 50 most dense urban areas. Dhaka is a megacity of 17.6 million and is the most densely-settled city in the world at 44,000 people per square kilometer. Mumbai, the world's 6th largest city with 19.3 million people, is also its 2nd densest, at 32,300 people per square kilometer.	 Mumbai is one of the world's largest and densest cities, with striking inequality, as visible in this drone image. <i>Photo by Johnny Miller.</i>	- Large geographic extent, sometimes forming 'megaregions' of hundreds of thousands of square kilometers of built-up area - Dense built-up area of impervious surfaces creates stormwater and urban heat island problems - Megacities often have tremendous inequality, housing some of the richest and most impoverished people in close proximity (e.g., Mumbai in (A)) - Large populations often mean high burdens on infrastructure: grey (freshwater distribution systems and electrical grids struggle to deliver adequate water and power; transportation of all types is overcrowded, etc.), green (parks can be overused and soils heavily compacted, urban forests can be inadequate), and blue (waterways are polluted and/or overused for recreation, bathing, irrigation) - Multiple, potentially overlapping or conflicting layers of governance in megacities and megaregions can complicate coordination of services, land use planning, etc.
Sprawling metropolis <i>HIGH total population, LOW population density</i>	Not all cities are densely populated. In many parts of the world (Canada, United States, Australia, Japan), cities sprawl across large metropolitan areas and have relatively low or middling population densities (compared to other similarly-sized cities). Of the 80 most populous cities in the world, the cities with the lowest densities (under 2,500 people per square kilometer) are all in the U.S. or Australia. For instance, Chicago and Hong Kong have relatively similar total populations (8.8 and 7.2 million, respectively), but while Hong Kong is the third most dense city in the world (at 25,700 people per square kilometer, in a total geography of 1,1073 km²), Chicago is ranked 95th in density with just 1,300 people per square kilometer in a much larger geography (over 28,000 km²). Atlanta is the least dense of the world's largest cities, with a population of 5.2 million spread over more than 21,000 km² resulting in a density of just 700 people per square kilometer.	 Chicago's Lake Michigan shoreline and sprawling north side at night. <i>Photo by Jess Vogt.</i>	- Large geographic extent and low population density may result in an inefficient use of space and resources (e.g., in transportation as people move around a relatively dispersed city) - Lower population density can afford opportunities for both large greenspaces such as parks, nature preserves, etc., as well as smaller patches such as yards, gardens, boulevards, etc. - (For some cities) Higher rates of home ownership due to lower population densities and the greater relative availability of single-family residential housing (e.g., Philadelphia; Taylor 2009) - The legacies of social and ecological patterns are visible in these cities, e.g., historical (and sometimes modern) racial discrimination in home mortgage practices creating inequalities in home ownership and clustering of racial groups into neighborhoods

Continued

Planned, new city <i>LOW total population, HIGH population density</i>	Rarely, cities may have relatively high population densities but a low total population size. Many smaller cities in China meet these criteria. In newer, planned cities that have been built very rapidly by the Chinese government in an effort to move more than 250 million people into cities, dense high-rise residential housing is replacing traditional, less dense housing in new agricultural and industrial centers, to create places for workers to live (Johnson 2013). However, because of the way administrative boundaries work in China, this high density in and near city centers is not reflected in calculations from country-reported total population and municipal area. Chinese municipalities are called county-level cities, and the complex of cities within a province exhaustively cover the entire area, meaning that sometimes large rural and agricultural areas are included in municipal limits and thus calculations of city population densities.	 High density residential buildings being constructed in Liaocheng, China, a city of just 677,000 residents – relatively small by global standards – as of 2015. Photo by Justin Jin.	- High density can mean large impervious surface areas, but proper planning can also yield large greenspaces - Rapid development may result in high resource use and throughput (waste) - In China, many of these cities displace people from traditional communities as they replace farmland and rural dwellings with impervious pavement and high rises, and replace farmland work with factory jobs and high unemployment, causing significant social and emotional impacts on the newly-urban residents (Johnson 2013)
Small- and medium-sized cities and towns <i>LOW total population, LOW population density</i>	The vast majority of the cities, towns, and communities that people reside in have relatively low total population sizes and low population densities. The UN reports that, “In 2018, there were 467 cities with between 1 and 5 million inhabitants and an additional 598 cities with between 500,000 and 1 million inhabitants” (United Nations Population Division 2019b, p. 2). And yet globally half of urban residents live in cities of less than 500,000 people (United Nations Population Division 2018). Small towns and cities may be growing rapidly in total population, density, and/or geographic extent, which is the case for many smaller cities in Africa, which is currently the most rural continent (United Nations Population Division, 2019b). In other parts of the world, such as the United States, these smaller cities are actually decreasing in population and density. Detroit, for instance, was once a city of over 1.8 million people (in the city proper) in the 1950s when it was a peak manufacturing hub in the United States. However, as of 2018, its population is just under 700,000 (though the urban agglomeration contains 3.6 million).	 Detroit's population decline has resulted in extensive vacant houses which have been demolished in the past decade yielding acres of vacant land inside Detroit city proper, as seen while flying over Detroit. Photo by Jess Vogt.	- Highly varied social and ecological dynamics depending on country, geography, climate, configuration, social and political dynamics, - The large number of small and medium cities and towns with low populations and population densities can offer lots of opportunities for innovation in planning, management, development, etc., in order to optimize outcomes for unique local social and ecological conditions - The variation in social and ecological dynamics makes it difficult to generalize or transfer results of urban social-ecological research from one urban area to another - In cities in the post-industrial “Rust Belt” in the United States (e.g., Detroit, at left), urban centers are often decreasing in population and density, as people (often Caucasian in race in the so-called “white flight”) leave cities for the surrounding suburbs, which then sprawl out across a region. This can deepen racial disparities in access to urban amenities and services.

Fig. 3, Cont'd

While the terms frameworks, theories, and models are used interchangeably by many scholars, we use these concepts in a nested manner to range from the most general to the most precise set of assumptions made by a scholar. . . . [A] *framework* is intended to contain the most general set of variables. . . . It provides a metatheoretical language to enable scholars to discuss any particular theory or to compare theories. A specific *theory* is used by an analyst to specify which working parts of a framework are considered useful to explain diverse outcomes and how they relate to one another. . . . *Models* make precise assumptions about a limited number of variables in a theory that scholars use to examine the formal consequences of these specific assumptions about the motivation of actors and the structure of the situation they face (Ostrom, 2010: 646; emphasis added).

From the standpoint of SES research, frameworks do two things: First, they provide a common language for scholars and practitioners examining a system or set of problems through multiple disciplinary lenses. Urban SES research requires the integration of multiple disciplines in order to account for the complexity of modern environmental problems. Interdisciplinary research is challenging and frameworks help define and redefine terms for cohesive and widely applicable conceptual analysis. A good framework's generalizable language usable in subsequent models and theory for explaining urban phenomena. Furthermore, for a holistic understanding of urban SESs, it is necessary to acknowledge the myriad decisionmakers, the constant changes in human and natural elements over time, the presence of feedbacks between ecological and social subsystems, and the uncertainty in drivers, interactions, and outcomes in cities (Alberti, 1999). Frameworks can help organize and describe these properties.

Second, frameworks provide a structure enabling scientific inquiry and diagnosis, helping researchers and managers figure out how the components in urban areas interact and thereby help understand what is guiding observed outcomes (Cox, 2011; Partelow, 2018). Frameworks with nested components in particular can help researchers unpack complex systems (Cox, 2011). SESs tend to be nested—that is, specific social and ecological elements are nested within larger social or ecological subsystems, which are—for urban systems—nested within urban areas as a whole. For instance, on the ecological side, trees might be in a small forested area that is within a city public park that is located adjacent to and within a river's catchment basin that drains into a regional watershed. On the social side, a single individual is part of a household that may live in a larger apartment building that may be part of a housing project that is located within a neighborhood that is part of one of many political wards that together make up the administrative units of a city. Frameworks can help conceptualize the nested nature of urban SESs as well as the interactions between social and ecological components within and across levels of nestedness (see also Cash et al., 2006 for an excellent discussion of the levels of SESs).

Comparing Frameworks in Urban SES Research

In part because of the interdisciplinarity required for studying urban areas (see also the next section on “Urban Ecosystems—A Related Concept”), there is no single framework universally used. Therefore, three frameworks are described below—the Human Ecosystem Framework (Pickett et al., 1997), the Ecosystem Dynamics Framework (Grimm et al., 2000), and the Urban Ecology Framework (Alberti et al., 2003). Fig. 4 displays the graphical representations of each framework, while Table 2 compares how the frameworks conceptualize the social and ecological elements of urban SESs. (Title Case is used in Table 2 and through this section to identify the language and terms used by the original authors to describe the subsystems and components of their framework.)

The Human Ecosystem framework (Fig. 4A) was first applied to cities by Pickett et al. (1997), who adapted the framework proposed by Machlis et al. (1997) for ecological research more broadly. The framework separates social and ecological subsystems, using a hierarchical approach to identify a set of nested components for each subsystem. The framework is comprised of four variable tiers with three major subsystems: the Human Social System, and Resource System, within which is nested Ecosystem Resources (Machlis et al. (1997)). The framework uses the ecosystem concept from traditional ecology, seeking to use the framework as a tool to instruct how humans might be added to ecosystems in urban areas (Machlis et al. (1997)). Intended for researchers with a stronger background in ecology and natural phenomenon, Pickett et al. (1997) provide ample detail in the nested social system, and theories of spatial heterogeneity and hierarchy have a strong emphasis in the framework (the idea of Patch Mosaics appears in the Ecological Processes box of the framework in Fig. 4A).

The Ecosystem Dynamics framework (Grimm et al., 2000; Fig. 4B) was influenced by Pickett et al. (1997) but is more rooted in the social, cultural, and economic sciences and focuses on understanding the influence human activities have on biophysical properties of urban systems. According to these authors, “Human perception, choice, and action are often the phenomena that drive political, economic, or cultural decisions that lead to or respond to change in ecological systems” (Grimm et al., 2000, p. 572). Following this idea, the framework prioritizes human actions as drivers of executing policy, ultimately leading to change in ecological systems (Grimm et al., 2000). Uniquely, the Ecosystem Dynamics framework identifies urban Land Use as a central component mediating the impact of Environmental Context and Societal Patterns on Ecological Patterns (which then feedback on Environmental Context and Societal Patterns via Ecological Conditions and Human Perceptions and Attitudes, respectively; Pickett et al. (1997)).

The Urban Ecology framework (Alberti et al., 2003; Fig. 4C) views cities as emergent phenomena with dynamic interactions among socioeconomic and biophysical forces. The highly integrated framework organizes all human and ecological elements in urban systems into four subsystems: Drivers, Patterns, Processes, and Effects/Changes (Alberti et al., 2003). Unlike Pickett et al. (1997), Grimm et al. (2000), and Alberti et al. (2003) lacks an explicit distinction between social and ecological elements highlighting the intractable connections between social and ecological subsystems in cities. The absence of explicitly defined social and ecological systems in the headings of components necessitates an interdisciplinary approach to studying urban systems.

All three frameworks facilitate the integration multiple disciplines to assist in hypothesis testing for interactions in urban SESs, but represent urban social-ecological system slightly differently, in part due to the different applications, goals, and intended users of the frameworks. While they differ in their portrayal of social and ecological subsystems, the nestedness of components, as well as how interactions and feedbacks are represented, they all have been widely used by the original authors as well as subsequent scholars to structure analyses of urban SESs.

Fig. 4 Three widely-cited frameworks for describing urban systems: (A) The Human Ecosystem Framework, (B) The Ecosystem Dynamics Framework, and (C) The Urban Ecology Framework. [https://doi.org/10.1641/0006-3568\(2000\)050\[0571:IATLT0\]2.0.CO;2](https://doi.org/10.1641/0006-3568(2000)050[0571:IATLT0]2.0.CO;2); (C) Alberti M (1999) Modeling the urban ecosystem: A conceptual framework. *Environment and Planning B: Planning and Design* 26(4): 605–630.

Table 2 A comparison of selected frameworks for studying urban social-ecological systems.

Framework	Social elements	Ecological elements	Integration
Human ecosystem (Pickett et al., 1997)	Divides up the social subsystem into Social Institutions, Social Cycles, and Social Order, with nested social elements within each, since ecologists are less familiar with social dynamics. Considers Cultural and Socio-Economic Resources in Resource System along with Ecosystem Resources	Ecological subsystem details are surface level due to ecologists' presumed familiarity with Ecological Processes (Energy, Water, Nutrients, Materials) and Patterns (Species, Soil, Vegetation)	Some parts of social systems in urban areas not considered independent from ecological phenomena (e.g., Cultural and Socio Economic Resources are considered together with Ecosystem Resources). Graphically, subsystem components are depicted as interacting with one another and then the Human Social and Resource System interact at a higher level
Ecosystem dynamics (Grimm et al., 2000)	Humans are connected to Ecological Patterns and Processes primarily through Land Use. Human Perceptions impact Societal Patterns and Processes (which impact Land use)	Land Use is a mediator for the influence of Societal and Environmental Context on Ecological Processes, which then feedback on Human perceptions and Ecological conditions	Coarse-Scale (climate, geology, and history) Environmental Context and Societal Patterns and Processes (culture, demography, and social institutions) are linked through their effects on Land Use, but Societal Patterns also directly influence Ecological Conditions
Urban ecology (Alberti et al., 2003)	A focus on the higher-level urban Drivers, Patterns, Processes, and Effects/Changes eschews separation of urban components into social and ecological subsystems. Urban dynamics visualized as a single feedback loop where both social and ecological Drivers (e.g., Population Growth, Climate) affect observed Patterns (e.g., of Land Use and Land Cover), which influence ecological and social processes (e.g., Runoff, Community Development). Processes in turn influence both Patterns as well as the Effects/Changes observed in cities (e.g., Biodiversity, Human Behavior)

Urban Ecosystems—A Related Concept

An article on urban social-ecological systems would not be complete without a brief discussion of the related concept of urban ecosystems and field of urban ecology. To be fair, most studies of urban SESs would likely be classified as urban ecology. Indeed, the phrases “urban social-ecological systems” or “urban social-ecological system” appear in a fraction of the academic search results as “urban ecology,” “urban ecosystems,” or “social-ecological systems” (Table 3). Urban ecology is the study of cities as ecosystems. In a review of the history of the field, McDonnell (2011) defined the field as follows: “Urban ecology integrates both basic (i.e., fundamental) and applied (i.e., problem oriented) natural and social science research to explore and elucidate the multiple dimensions of urban ecosystems” (p. 9).

As a field of scholarship, urban ecology has really come into its own since the late 1990s, when ecologists truly began to dedicate themselves to the study of cities (McDonnell, 2011). Yet, sociologists, political scientists, planners, geographers and other social scientists had been studying urban dynamics for decades, and the “Chicago School” of sociology in particular began using ecological ideas to describe how cities functioned for people in the 1940s (McDonnell, 2011). These social scientists generally used the theories, frameworks, and methods from their own disciplines in studying urban systems, however. Modern urban ecology as a field is more interdisciplinary and even transdisciplinary (interdisciplinary research that involves stakeholders and practitioners). The three frameworks for understanding urban SESs discussed in the previous section are all rooted in the field of urban ecology. And out of this research has emerged 13 “principles” of urban ecology (Pickett and Cadenasso, 2017; Table 4).

One of the most common way of conceptualizing urban ecology is as ecology “in,” “of,” and “for” cities. Broadly, the “ecology in cities” approach examines classical ecological questions of ecological functioning, nutrient cycling, species diversity, and patterns of

Table 3 Number of search results for phrases related to urban social-ecological system research in three major academic search engines. Search conducted on January 11, 2020.

“social-ecological system” OR “social-ecological systems”	About 17,500	3629	1561

Table 4 Thirteen principles of urban ecology.

1. Cities and urban areas are human ecosystems in which social-economic and ecological processes feedback to one another
2. Urban areas contain remnant or newly emerging vegetated and stream patches that exhibit ecological functions
3. Urban flora and fauna are diverse, and this diversity has multiple dimensions (e.g., taxonomy, phylogenetics, function, geographic origin)
4. Human values and perceptions are a key link mediating the feedbacks between social and ecological components of human ecosystems
5. Ecological processes are differentially distributed across the metropolis and the limitation of services and excess of hazards is often associated with the location of human communities that are poor, discriminated against, or otherwise disempowered
6. Urban form is heterogeneous on many scales, and fine-scale heterogeneity is especially notable in cities and older suburbs
7. Urban form reflects planning, incidental, and indirect effects of social and environmental decisions
8. Urban form is a dynamic phenomenon and exhibits contrasts through time and across regions that express different cultural and economic contexts of urbanization
9. Urban designs and development projects at various scales can be treated as experiments, and used to expose the ecological effects of different design and management strategies
10. Definition of the boundaries and content of an urban system model is set by the researchers based on their research questions or the spatial scope of its intended application
11. Urban comparisons can be framed as linear transects or as abstract gradients, and the abstract comparisons acknowledge the spatial complexity of urban heterogeneity
12. Urban land covers and land uses extend into and interdigitate with rural or wild land covers and uses
13. The flux of water, including both clean water supply, waste, and stormwater management, is of concern to urban and urbanizing areas worldwide, and connects them explicitly to larger regions

"Principle" in this treatment means components of a potential theory or framework.

Principles from Pickett STA, Cadenasso ML (2017) How many principles of urban ecology are there? *Landscape Ecology* 32: 699–705. <https://doi.org/10.1007/s10980-017-0492-0>.

competition, predation, etc., as they are applied to the ecological elements of cities (see also the discussion in McPhearson et al., 2016). The "ecology of cities" approach, on the other hand, considers the entire city itself as an ecosystem and examines human drivers of (and how human systems are impacted by) ecological patterns and processes. Finally, the "ecology for cities" approach has recently emerged as a transdisciplinary approach that seeks to apply research and understanding of urban social-ecological systems to practical policy and decision making for the sustainability of cities (Childers et al., 2015; Grove et al., 2016; Schwarz and Herrman, 2016).

Conclusion

This article has reviewed definitions of social-ecological systems, urban, and urbanization; described and compared frameworks for studying urban areas as social-ecological systems; and discussed the related concept of urban ecosystems and urban ecology. Urban social-ecological systems research is an emerging field building on at least three decades of urban ecological research since the 1990s but with no single unifying conceptual framework or theories to date. However, given that a majority and growing proportion of the human population lives in urban areas, understanding the social and ecological patterns and processes at work in cities will play an important role in making sure that cities are both livable for people and environmentally sustainable.

Abstract

Urban forests are all the trees, forests, associated vegetation growing in or very near the cities, towns, and communities where people live, work, and play. What makes urban forests different from forests outside urban areas is their existence in dense areas of human settlement—cities, towns, suburbs, etc. What qualifies as urban from the standpoint of urban forestry includes a range of population sizes or densities (parallel to the Ellis et al. (2010) mapping of anthropogenic biomes, or anthromes, to human population densities): There is no minimum threshold for how many people must live in a community for it to have an urban forest, and the term urban forestry is applied to the management of populations of trees in communities of all sizes. This article discusses the definitions of urban, urban forests, and urban forestry, describes the biophysical characteristics of urban forests and what makes urban forests different from non-urban forests, and details the ecosystem services and disservices provided by urban forests.

Urban Forests and Urban Forestry

Urban forests are all the trees, forests, and associated vegetation and ecosystem components growing in or very near the cities, towns, and communities where people live, work, and play. These “dense settlements”—inclusive of large urban areas and their suburbs, but also towns, etc.—are one of the levels of anthropogenic biomes, or “anthromes,” that has the highest human population density and intensity of impact (Ellis et al., 2010), and urban forests can help mitigate negative impacts. Urban forests can include trees planted in many different types of growing spaces: in the parkways (i.e., boulevards, tree lawns) along streets and next to sidewalks in cities (called “street trees”); in public parks or cemeteries; trees in front or back yards (i.e., private gardens) on residential property; on institutional properties such as school or hospital campuses or business or industrial parks; along highways; growing spontaneously in vacant lots and along alleys; trees in remnant natural areas or planted woodlands; and more (Fig. 1). Because they are co-located in places inhabited by people, urban forests include not only the trees and soil and other abiotic and biotic features in the surrounding growing environment, but also the people living in cities who impact the urban forest.

The science and practice of planting, maintaining, monitoring, and managing the populations of trees in urban areas in order to ensure the provision of the benefits these trees and forest produce for people is called “urban forestry.” Urban forestry—sometimes also called “urban forest management”—consists of a suite of activities, including but not limited to planting, maintaining (pruning, watering, mulching, staking, etc.), and removing trees, but also tree inventory, pest monitoring and plant health care, tree risk assessment, planning for future tree planting and management, and even educating the general public on the benefits and care of trees and advocating on behalf of the urban forest. Performed under ideal circumstances—that is, when experienced urban forest managers have access to complete data on their urban forest, as well as adequate time, labor, and sufficient monetary and quality material resources—urban forest management ensures the net benefits provided by the entire urban forest are maximized (see the section below on “The Benefits and Values of Urban Forests”). Urban forestry is closely connected to the field of *arboriculture*, or the “practice and study of the care of trees and other woody plants in the landscape” (ISA, 2019). Whereas urban forestry deals with entire populations of trees in cities, arboriculture is more often concerned with the care and maintenance of single trees.

In the sections that follow, I describe the biophysical aspects of urban forests, what makes urban forest different from non-urban forests, and the ecosystem services and disservices provided by urban forests.

Fig. 1 The many types of trees in the urban forest. All photos taken by the author.

Biophysical Aspects of Urban Forests

What Is “Urban”?

What makes urban forests distinctly different from forests outside urban areas is their existence in areas of human settlement. In the anthromes terminology, this includes “dense settlements” (urban and mixed settlements) and populated “seminatural lands” such as residential woodlands and populated woodlands (Ellis et al., 2010). In order to understand urban forests as a central component of these anthromes, it is crucial to understand what “urban” means in this context. What is considered urban for the sake of urban forests varies around the world and even from community to community within a single country, but generally means the

communities where people live. Sometimes, the term “urban” is defined by the number of people living in a community or population center, sometimes also with respect to the density of people living in an area. For instance, the US Census Bureau defines the term “urbanized areas” as those having 50,000 or more people, while “urban clusters” have between 2500 and 50,000 people; “rural,” then, is a term inclusive of all areas that do not qualify as urban ([US Census Bureau, 2018](#)). This definition of urban is not consistent across the entire world, or even all of North America: Statistics Canada, responsible for the Canadian census, for instance, defines urban as all population centers of greater than 1000 people with a density of greater 400 people per square kilometer (1036 people per square mile) ([Statistics Canada, 2017](#)). And in Africa, for example, urban definitions range considerably—containing more than 2000 inhabitants (Ethiopia, Kenya), more than 5000 inhabitants (Zambia), or more than 10,000 inhabitants (Senegal)—or, in Algeria, are defined instead by the number of “constructions” (100+, spaced 200 m or less apart; [United Nations Statistics Division, 2011](#), as summarized in [Francis and Chadwick, 2013](#)).

What qualifies as urban from the standpoint of urban forestry can actually include a range of population sizes or densities. Generally, there is no minimum threshold for how many people must live in a community for the it to have an urban forest, and the term urban forestry is applied to the management of populations of trees in communities of all sizes. Because of this, sometimes the term “community forestry” is preferred by smaller towns for which the term “urban” may not resonate. The US Forest Service, for instance, uses the phrase “urban and community forestry” to refer to the program within the Forest Service that administers to urban forests. However, “community forestry” and “urban forestry” are not interchangeable in all parts of the world. In Canada for instance, “community forestry” refers to communities that have a significant economic dependency on forest resources and the forestry industry (i.e., forest-dependent communities; [Duinker et al., 1994](#)). In Europe also, the term “community forestry” was also initially linked not to modern concepts of “urban forestry” but instead to heritage woodlands in smaller towns or more rural areas that are managed by the local community ([Konijnendijk et al., 2006](#)).

Urban Forest Characteristics

Most readers will be more familiar with the idea of a “forest” than with an “urban forest,” despite the fact that more than 50% of the global population lives in some type of city or town, and 29% live in so-called urban anthromes ([Ellis et al., 2010](#)). City dwellers may experience the urban forest on a more regular basis than “natural” forests outside cities. Urban forests differ from non-urban forests in several essential ways. First, the image of a “forest” may conjure expansive stands of trees, shrubs, and other vegetation with a closed canopy of leaves overhead letting little light through to the forest floor, which may be dense with leaf litter and ground vegetation. Some parts of the urban forest may look similar to non-urban forests, for instance, if there are remnant patches of native forest that have been enclosed by urban development and set aside as parks, nature preserves, or backyard woodlands. There may also be areas of planted (non-remnant) forest within a city that share this more traditional forested character. Whether planted or remnant, these areas are sometimes called urban forest natural areas, naturalized areas, forest patches, urban woodlands or woodlots, or forested parks. These areas likely include more than just trees, but also shrubs and herbs as ground cover, and depending on quality, may contain habitat for urban wildlife including small mammals, insects, and birds. Urban forest natural areas may about bodies of water that are near or within urban areas, such as streams, rivers, ponds, lakes, or canals. The growing conditions for trees in these types of areas are more likely to mimic those for trees in natural areas outside of cities, and the soils, hydrology, nutrient flows, microclimate, and ecology may be more similar to natural areas.

However, urban forests also include trees growing outside of more natural or naturalized areas within cities—in parks, the front or back yards of residential properties, along streets, etc. These types of growing conditions are much different from the semi-natural conditions of urban forest natural areas. Both above and belowground growing space may be more constrained, especially for trees highly constructed spaces. For instance, trees growing in a tree pit are especially constrained: tree pits are small growing spaces with perhaps only a couple square meters of growing substrate (soil, sometimes mixed with gravel or other medium), often found along streets, in plazas, parking lots. The base of a tree in a tree pit is likely surrounded on all four sides by concrete paving impervious to water, and the area immediately adjacent to the tree trunk may be covered with a metal grate that, if not properly sized, may interfere with the root flare and healthy trunk growth. Belowground, tree roots must compete with urban infrastructure such as buried power and cable lines, storm and sanitary sewer pipes, gas lines, building and road foundations, etc., not to mention cope with high levels of soil compaction, soil nutrient imbalance, and inadequate soil drainage (or conversely, poor water retention). Aboveground, these trees may be heavily pruned so that they do not interfere with urban infrastructure such as buildings, fences, signage, street lights, above ground power and cable lines, etc., or may have limited exposure to light due to shading by tall urban buildings. Because of this suite of constraints, trees in constrained urban areas may be in poor condition, of small size and sub-optimal form, and experience high mortality rates and short life spans.

Yet other trees in some urban spaces may experience more favorable growing conditions. For instance, trees in high-quality urban parks may have relatively unlimited growing space, be well-cared for (through regular pruning and watering, pest management, etc.), and even may have access to additional nutrients (either through direct fertilizing of the tree, or as a byproduct of fertilizing the nearby turf grass). They may be growing in a wide-open area free of competition with other trees or other urban infrastructure. These high-quality growing conditions may lead to long-lived trees that grow large and provide significant benefits.

The Benefits and Values of Urban Forests—Ecosystem Services

Urban forests are important for cities because trees provide benefits that have substantial value for the people who live in those cities. This section will discuss how urban forests produce benefits, how these benefits are valued, and how this value is calculated.

Structure, Function, Benefits, and Value

The mechanism through which urban trees and forests provide value to people can be conceptualized as the structure-function-benefits relationship (Fig. 2). The structural characteristics of urban trees—such as tree size, species, etc.—and urban forests—such as the extent of urban tree canopy cover across all or a portion of an urban area—contribute to the ecosystem functions provided by those trees and forests. Trees and forests, whether in urban or non-urban areas, perform a variety of ecosystem functions, including regulating functions such as climate management through shading and evapotranspiration; biodiversity functions such as providing nesting habitat for urban wildlife; production functions such as producing edible fruits and nuts; and “information functions” (c.f., de Groot et al., 2002) such as the aesthetic and scientific opportunities afforded by the existence of urban trees (Table 1). These ecosystem functions, when viewed through an anthropocentric lens, translate into benefits and value for people, often termed ecosystem services. (In urban forestry, “benefits” is often used synonymously with “ecosystem services”. In the broader ecosystem services literature, *ecosystem services* are “the benefits humans obtain from ecosystems” (Millennium Ecosystem Assessment, 2005, p. v). However, urban forest discourses more frequently use the more general “benefits” term in both the scholarly literature as well as in communications with the general public.) For instance, the water regulating functions of trees benefit people when trees are used as part of green infrastructure-based solutions for managing stormwater in urban areas.

Urban forest structure and function are biocentric ways of conceptualizing the importance of the urban forest. *Biocentric*, in this context, refers to the intrinsic value of trees and forests—that is, nature for nature’s sake; the urban forest will have these functions regardless of what if any value humans place on them. All of the functions listed in Table 1 (with the exception of information functions) can be considered biocentric. Urban forest benefits and value, on the other hand, are anthropocentric concepts. *Anthropocentric* refers to the value of trees and forests explicitly for human benefit and use; that is, the functions of urban forests would have no benefits or value without that which humans place on them. Urban forestry and urban forest management are mostly anthropocentric, which makes sense given the explicit consideration of urban forests as trees located in the places where people live and work.

The structure-function-benefits relationship has implications for how people think about and manage urban forests. Urban forests may be managed according to goals that align with the biocentric, intrinsic value that structure and function has. For instance, managers may have goals for species composition (e.g., a single species can account for no greater than 10% of all public trees) or size distribution (e.g., have more small, young trees than large, mature trees in the urban forest) of their urban forest. These types of biocentric goals often imply a rationale related to urban forest function (e.g., a diverse species composition decreases vulnerability of the urban forest to taxa-specific pest or disease outbreak). On the other hand, anthropocentric urban forest management goals related to the benefits and values of trees might consider management of the urban forest in order to provide a specific level of benefits (e.g., gallons of stormwater diverted from runoff in order to prevent the city from needing to issue capital improvement funds to allow the public works department to install larger pipes when updating stormwater infrastructure).

The list of particular benefits provided by urban forests is extensive, and the benefits of trees is one of the more well-researched areas of urban forestry as a scholarly discipline. Urban forest benefits can generally be thought of as falling into three categories: environmental benefits, including those related to urban environmental quality issues such as air quality, water quality, and microclimate, as well as biodiversity and conservation benefits such as wildlife habitat; social benefits such as human quality of life,

Fig. 2 Urban forest structure such as tree size and species impact how urban trees and forests perform key ecosystem functions such as climate regulation (through shading and evapotranspiration), which in turn impacts the production of benefits such as reducing urban temperatures. Since these benefits often have real value to people living in urban areas, they are often translated to economic terms, such as the decreased electricity costs resulting from reduced need for air conditioning. Note that urban forest structure and function are “biocentric” concepts while benefits and value are “anthropocentric” concepts. See main text for a more detailed discussion of structure, function, benefits, and value in the context of biocentric and anthropocentric ideas of the urban forest.

Table 1 Select ecosystem functions performed by trees and forests in cities.^a

Function	Explanation
<i>Regulation functions</i>	<i>The “maintenance of essential ecological processes and life support systems” (de Groot et al., 2002, p. 396)</i>
Gas regulation	Trees photosynthesize, taking in carbon dioxide and releasing oxygen.
Climate regulation	Through shading and evapotranspiration trees have a cooling effect on the local microclimate, while larger groups of trees or forested areas such as parks contribute to the urban breeze cycle, whereby as the hot air over paved areas and buildings rises, drawing in the cooler air from adjacent vegetated areas.
Water regulation	Tree canopy and roots slow the infiltration of stormwater and help manage runoff in urban areas, as well as filter, retain, and store fresh water (e.g., in retention ponds or local bodies of freshwater).
Soil retention	Tree roots make sure that soil is not eroded, particularly along steep slopes (e.g., next to highways).
Waste treatment	The leaf surface area provided by tree canopies filters the air of particulate matter and pollutants.
Biological control	A diverse species composition within the urban forest helps reduce vulnerability to infestation by a taxa-specific pest or disease.
<i>Habitat functions</i>	<i>The function urban trees of urban forests have of providing habitat for plant and animal species.</i>
Refuge	Trees and forests provide living spaces and foraging resources for wildlife.
Nursery	Trees and forests provide habitat for wildlife to use to reproduce (e.g., nesting locations for birds, squirrels).
<i>Production functions</i>	<i>Trees and urban forest can, in certain cases, provide natural resources for human use.</i>
Food	Trees produce edible fruits, nuts, and seeds.
Raw materials	As they grow and mature, trees have increased wood volume, which can be used for human purposes at the end of their urban life.
<i>Information resources*</i>	<i>Trees and urban forests can “provide opportunities for cognitive development” (de Groot et al., 2002, p. 396)</i>
Aesthetic*	Trees and urban forests produce greenery and flowers that have aesthetic appeal for humans in urban areas.
Recreation*	Trees and urban forests in cities are physical spaces for—as well as encourage individuals to—exercise and recreate outside in cities.
Scientific and education*	Trees and urban forests can provide opportunities for scientists and the general public alike to study and learn about nature.

Ecosystem functions list borrowed in part from de Groot et al. (2002) typology of ecosystem functions. An * indicates an ecosystem function that is dependent on the presence and values of humans in order to be a function (anthropocentric).

^aSome readers may be familiar with the Millennium Ecosystem Assessment (2005) categories for ecosystem services (provisioning, regulating, cultural, and supporting). The above table does not use these categories here because the table presents a list of ecosystem functions, which are slightly different from services: ecosystem functions are about what an ecosystem does as a system of biotic and abiotic components, while ecosystem services are about what an ecosystem provides to people. Ecosystem functions can be translated into ecosystem services by applying an anthropocentric filter to examine how the functions of an ecosystem benefit humans. See main text for a more detailed description of the translation of urban forest structure and function into benefits and values for people.

human health, and community social capital; and economic benefits such as those related to property values, utilities expenditures and investments such as electricity and water and associated infrastructure, and economic development. Table 2 provides a semi-comprehensive but non-exhaustive list of the benefits of urban forests, since researchers are constantly investigating new benefits. In particular, significant new research on the social and human health benefits of urban forests is emerging through the work of several dedicated communities of scholars.

Calculating Urban Forest Economic Value

Urban forest benefits are sometimes translated into dollars or monetary terms to express the value that urban forests have in economic terms. Using methods from the field of ecological economics, urban forest researchers have monetized benefits such as stormwater management, air pollution, reduced energy costs, aesthetic benefits manifesting as property value increases, and even improvements in physical and mental aspects of human health. Table 3 describes select studies that have used scientific research to empirically examine the connection between urban forest structure, function, benefits, and, for select studies, economic value.

i-Tree: A case study of calculating urban forest value

One of the most dedicated and long-term efforts to translate urban forest structure and into benefits and economic value for people is the effort by researchers with the US Forest Service and Davey Resource Group to develop i-Tree (www.itreetools.org). i-Tree is a suite of online software tools into which an urban forest researcher or manager can enter data about the structure of a tree population (either by uploading a spreadsheet of a tree inventory or by accessing existing tree canopy cover data, where available) and get back data about some of the most commonly-valued benefits (stormwater, aesthetics/property value, energy, air quality, and carbon dioxide) produced annually by a tree population as well as the dollar value of these benefits. (Note that because the i-Tree software automatically quantifies both the benefits (e.g., kilowatt hours of electricity conserved due to the cooling benefits of trees) as well as the economic value of this benefit (e.g., dollars saved on electricity), the term “benefits” when used by i-Tree means both benefits and value.) A simple version of i-Tree built for entering data for just a single tree can be found at the National Tree Benefits Calculator (<http://www.treebenefits.com/calculator/>). Fig. 3 shows the results from the National Tree Benefits Calculator for the benefits provided by a 12-in. (30 cm) diameter red maple (*Acer rubrum*)—a common urban street tree planted across the world—growing on a single-family residential property in Chicago, Illinois.

Table 2 A semi-comprehensive list of the benefits of urban trees.

<i>Environmental</i>	<i>Social</i>	<i>Economic</i>
<i>Air quality</i>	<i>Urban quality of life</i>	<i>Property value</i>
Produce oxygen	Enhance urban quality of life	Increase property, land value
Filter air	Provide outdoor recreation/leisure opportunities	Increase neighboring property value
Remove ozone	Provide nature in the city	Reduce time to sale for property sales
Remove carbon monoxide	Reduce noise and apparent loudness	Increase rental price for properties
Remove nitrogen dioxide	Decreased incidences of some types of crime	Increase property taxes
Remove particulate matter	<i>Human health</i>	<i>Utility benefits</i>
Remove smog	Create relaxed psychological states	Reduce expenditures on stormwater infrastructure
<i>Stormwater</i>	Averted premature death (e.g., decrease mortality from cardiovascular disease and upper respiratory illness)	Avoid investments in new power infrastructure
Reduce rate and volume of stormwater runoff	Decreased length of hospital stays following surgery	Provide potential for future carbon offsets
Reduce flooding damage	Improve mental health (e.g., decrease ADHD symptoms, reduce stress)	Save on annual heating/cooling costs
Reduce water quality problems	Improve physical health (e.g., decrease asthma rates, cardiovascular disease, and low birth weight)	Save on electricity costs
Recharge groundwater	<i>Community/social capital</i>	Save on fuel expenditures
<i>Carbon related</i>	Build a sense of community (stronger neighborhood ties)	<i>Economic development</i>
Reduce carbon dioxide emissions	Enhance a community's social identity and self esteem	Increased tourism revenue
Store/sequester carbon	Provide a sense of place	Increased business activity
<i>Energy related</i>	Provide settings for significant emotional and spiritual experiences	Contribute to the economic vitality of the community
Reduce annual energy use	<i>Individual human capital</i>	Provide returns on municipal investments
Reduce summer time energy use	Provide opportunities for inner city children to experience nature	<i>Pollution abatement</i>
Reduce seasonal cooling energy	Build skills associated with green trades	Reduce expenditures on air pollution removal
Reduce carbon dioxide emissions from power plants	Promote individual environmental responsibility	
<i>Microclimate</i>	<i>Aesthetic benefits</i>	
Provide shade	More pleasant urban environments	
Reduce solar radiation	Improve scenic quality	
Modify microclimate	Provide privacy	
Reduce relative humidity	Create seasonal interest and highlighting seasonal changes	
Reduce air temperature		
Reduce urban heat island effect		
Reduce glare/reflection		
Control wind		
<i>Biodiversity and conservation</i>		
Provide wildlife habitat		
Enhance biodiversity		
Provide stability to urban ecosystems		

Re-classified from a list presented by Roy et al. (2012) in their literature review of 115 studies, with additions from more recent literature as necessary.

Table 3 Examples of scientific studies that have provided evidence for select environmental, economic and social benefits of urban trees and forests.

<i>Benefit</i>	<i>Description of scientific study</i>	<i>Source</i>
<i>Environmental</i>		
Oxygen production	Used data on tree biomass from field plots in 16 cities across the continental US to extrapolate oxygen production by trees in US urban forests to be 61 million metric tons, but because of the large amount of oxygen already in the atmosphere, notes that the value of oxygen production by urban forests to society is negligible.	Nowak et al. (2007)
Air pollution removal*	Used data from field plots in 10 US cities to model particulate matter (PM _{2.5}) removal by urban forests and observed average air quality improvements in each city ranging from 0.05% to 0.24%, with an annual value to society ranging from \$1.1 million to \$60.1 million (2012 USD).	Nowak et al. (2013)
Cooling/temperature regulation	Used bicycle-sensed microclimate and weather data in combination with tree canopy cover data from Madison, Wisconsin, and observed that daytime air temperatures were inversely linearly correlated with tree canopy cover, and that temperatures were substantially lower for neighborhood blocks with canopy cover greater than 40%, and that the air temperature increases caused by high amounts of impervious surface cover can be offset by the cooling effects of trees.	Ziter et al. (2019)

(Continued)

Table 3 Examples of scientific studies that have provided evidence for select environmental, economic and social benefits of urban trees and forests.—cont'd

Benefit	Description of scientific study	Source
Stormwater management	Compared structure of street tree populations in 9 communities around Cincinnati, Ohio, and used i-Tree software to model stormwater benefits and observed greater stormwater benefits for those communities with greater tree canopy cover, and for those communities meeting the urban forest management standards of the Tree City USA program.	Berland and Hopton (2014)
<i>Social</i>		
Increased opportunities for recreation	Conducted surveys of park visitors and gathered data about urban forest structure in public parks in Berlin, Germany, and Salzburg, Austria, and found that visitors engaged in both active and passive forms of recreation and rated shaded (treed) areas as most important to passive relaxation activities.	Voigt et al. (2014)
Decreased mortality	Compared county-level mortality rates from 1990 to 2007 across 15 states impacted by emerald ash borer (EAB), and observed a decrease in cardiovascular- and lower-respiratory-tract illness-related mortality rates in counties not invested with EAB compared to counties with EAB infestations (which had thus experienced a significant loss of tree canopy in a short period of time).	Donovan et al. (2013)
Stronger community ties	Compared “greener” and “less green” areas of public housing complexes in Chicago in a number of studies conducted in the late 1990s, and observed greater social interaction among residents in greener areas, greater incidence of adult-child interactions, stronger social ties among neighbors, and a reported stronger feeling of belonging for residents in greener areas.	Kuo (2003)
<i>Economic</i>		
Increased business district retail sales*	Conducted surveys of residents in small and large towns and observed that for both size communities, shopping area streetscapes with trees were not only perceived as more pleasant and desirable by patrons but that patrons were willing to pay more for goods purchased in treed shopping areas compared to those without trees.	Wolf (2005)
Increased residential property value*	Compared 600 recently-sold single-family residential properties across six communities around Cincinnati, Ohio, and observed higher property sales prices for properties with higher urban tree canopy cover in the amount of \$780 (2012 USD) per every 1% increase in tree cover.	Dimke et al. (2013)

An * next to the benefit indicates that the study measured the economic value of the benefit.

National Tree Benefit Calculator

Beta

The National Tree Benefit Calculator was conceived and developed by
Casey Trees and Davey Tree Expert Co.

Fig. 3 The results of translating the structure of a 12" Norway maple (*Acer platanoides*) growing in a single-family residential land use area in Chicago, Illinois into urban forest benefits and value. Using the National Tree Benefits Calculator (<http://www.treebenefits.com/calculator/>).

Fig. 4 Comparing urban tree benefits for a 12-in. (30 cm) diameter red maple (*Acer rubrum*, a) grown on single-family residential land use in Chicago, Illinois, to a similarly grown pin oak (*Quercus palustris*, b), 18- and 24-in. (46- and 61-cm) red maples (c and d), the same 12-in. red maple grown on park or commercial land (e and f), or on single-family residential property in Atlanta or San Diego (g and h). Based on results from the National Tree Benefits Calculator (<http://www.treebenefits.com/calculator/>). Specifications used in the calculator are as follows: (a) Red maple (*Acer rubrum*), 12" diameter, Single-family residential, Chicago, Illinois (Northeast climate zone). (b) Pin oak (*Quercus palustris*), 12" diameter, Single-family residential, Chicago, Illinois (Northeast climate zone). (c) Red maple (*Acer rubrum*), 18" diameter, Single-family residential, Chicago, Illinois (Northeast climate zone). (d) Red maple (*Acer rubrum*), 24" diameter, Single-family residential, Chicago, Illinois (Northeast climate zone). (e) Red maple (*Acer rubrum*), 12" diameter, Park or other vacant land, Chicago, Illinois (Northeast climate zone). (f) Red maple (*Acer rubrum*), 12" diameter, Small commercial business, Chicago, Illinois (Northeast climate zone). (g) Red maple (*Acer rubrum*), 12" diameter, Single-family residential, Atlanta, Georgia (Southern climate zone). (h) Red maple (*Acer rubrum*), 12" diameter, Single-family residential, San Diego, California (Southern California Coastal climate zone).

The structure, function, benefits, and value provided by a tree are impacted by countless factors related to the tree itself, where it is growing, maintenance performed, and any number of additional variables in the surrounding community that might impact a tree's structure. The key factors considered by i-Tree calculations include species, size, land-use type, and the climate in which the tree is growing. Comparing the value of benefits for similar trees that vary only on one of these dimensions can be instructive towards understanding the connection between tree structure and benefits (Fig. 4). For instance, climate impacts not only how a tree grows but also the value of benefits such as heating and cooling energy savings. Of the major benefits valued by i-Tree (and the National Tree Benefits Calculator), for a 12-in. red maple tree growing in Chicago, Illinois, located in i-Tree's Northeast climate zone, the largest portion of a tree's value comes from property value benefits, followed by energy savings due to decreased consumption of natural gas. However, for the same 12-in. red maple tree growing in warmer climates, such as Atlanta, Georgia (located in the Southern climate zone) or San Diego, California (in the Southern California Coastal climate zone), while property values are still important (especially for San Diego where the housing market is highly competitive and residential real estate prices are high), natural gas energy savings from reduced heating needs are negligible (compare panels a, g, and h of Fig. 4).

The five major benefits (stormwater, property value, energy, air quality, and carbon dioxide) considered in i-Tree-based analyses are not the only benefits of urban trees (as illustrated by the extensive list in Table 2), nor are they the only benefits researchers have translated to economic values. Thus, the calculation of tree value provided by i-Tree and applications like the National Tree Benefits Calculator is a conservative estimate of the true value of an urban tree or forest. Researchers with the i-Tree team are currently working to expand the ability of this software tool—widely used by urban forest managers—to integrate value calculations for a larger list of tree benefits, including human health. For instance, a recent study considered four major human health-related benefits (birth weight, attention deficit hyperactivity disorder [ADHD], cardiovascular disease, and Alzheimer's disease) plus two additional urban quality-of-life benefits (school performance, crime), and found that the potential total annual value of urban trees and forests in the United States is between \$2.7 and \$6.8 billion (2012 USD) (Wolf et al., 2015). Incorporating this new research into tree benefits calculations will improve researchers' and managers' abilities to communicate the benefits of urban trees and forests to the general public and, importantly, urban policy makers. Additionally, researchers are working to expand the ability of i-Tree for use in a greater variety of locations around the world (currently i-Tree is most accurate in calculating benefits and values for urban trees and forests in the United States).

Externalities of Urban Forests—Ecosystem Disservices

The functions of urban trees and forest produce not only benefits or ecosystem services for people, but also “ecosystem disservices,” or negative consequences for people from nature (c.f., Lyytimäki and Sipilä, 2009). These “externalities” are public costs—that is, not captured in the private cost of a good or service. Externality-related costs are not paid for by any particular individual as part of the costs of the urban forest. Urban trees produce many types of ecosystem disservices that can be classified as either environmental or social (Table 4). Ecosystem disservices that might be classified as economic are better conceptualized as direct costs, though it

Table 4 Environmental and social ecosystem disservices produced by urban trees and forests.

<i>Environmental</i>	<i>Social</i>
<i>Water-related problems</i>	<i>Health problems</i>
Increased water consumption (especially in drought-plagued regions)	Allergies due to release of plant pollen
Drainage problems from tree root-sewer conflict	Attacks by insects/animals associated with urban forests (e.g., mosquito habitat)
<i>Debris/waste issues</i>	Increase of insects/animals acting as vectors for disease
Disposal of green waste generated during tree pruning/removal	<i>Safety concerns</i>
Disposal of debris/clutter from leaves and nuts/fruits/seeds	Obscured views/decreased traffic visibility
Disposal of debris during infrastructure repair due to tree conflicts	Risk to human safety from falling limbs
<i>Air pollution-related</i>	Actual increases in crime
Release of biogenic volatile organic compounds (BVOCs; air pollution)	<i>Aesthetic concerns</i> Darkness
Release of carbon dioxide during maintenance due to use of fossil-fuel powered equipment	Debris/clutter of leaves and nuts/fruits/seeds
Release of carbon dioxide during decomposition of tree or tree debris	Sap dripping on parked cars
<i>Ecosystem integrity</i>	Improper maintenance leads to displeasing form (e.g., topped trees, weed-filled vacant lots, excessive sprouting)
Displacing native species/escape of invasive species from urban forests	<i>Negative perceptions of trees/forests</i>
<i>Energy-related</i>	Fear of crime
Increased energy consumption due to improperly placed trees	Fear of disease
Increased energy consumption due to tree maintenance	Fear of insects or other animals
Loss of solar panel capacity due to shading by trees	Fears of forests and trees

Re-classified from a list presented by Roy et al. (2012) in their literature review of 115 studies, with additions from literature focused explicitly on ecosystem disservices (Lyytimäki and Sipilä, 2009; Dobbs et al., 2011; Lyytimäki, 2014). (Note that ecosystem disservices of trees in Roy et al. (2012) that might be considered economic costs are better conceptualized as either direct costs (cost of planting and irrigation, trees falling across power lines, etc.) rather than externalities or ecosystem disservices.)

should be noted that many of the disservices listed in Table 4 may be translated into economic value the same way the benefits listed in Table 2 may be translated into economic value. However, these values most of the time are not explicitly paid for by any particular actor associated with the urban forest, and thus are external (i.e., “externalities”) to the decision-making of individuals or groups with respect to urban forest management.

Conclusion

This article has described urban forests as all the trees, forests, and associated vegetation and ecosystem components growing in or very near the cities, towns, and communities where people live, work, and play. This includes trees planted along streets and boulevards, in parks, on private property, in vacant lots, and even those trees that spring up in unmanaged alleys or along transportation corridors. Urban forests produce significant benefits, or ecosystem services, for urban residents, but also have externalities, or ecosystem disservices. While this article has focused on the biophysical, or ecological, elements, there are also significant human influences on urban trees and forests.

Abstract

Urban forests are all the trees, forests, associated vegetation growing in anthromes with higher levels of population density (e.g., dense settlements and populated woodlands). This chapter describes the important human elements of urban forest ecosystems, including actors, ownership regimes, and management, the distribution of urban forest benefits, the direct costs of urban forests, and current conceptions of urban forest sustainability. The chapter concludes by presenting a comprehensive framework for understanding the many factors that shape urban forests as social-ecological systems of inseparable natural and human components.

Urban forests are by their very nature systems of both natural components (i.e., trees, etc.) and human components (i.e., people living in urban areas) found in anthromes (cf., [Ellis et al., 2010](#)) ranging from dense settlements to populated woodlands. Thus, in addition to considering the biophysical characteristics of the trees and forested areas that make up urban forests, it is also necessary to consider the human elements of the urban forest.

This article examines how the human elements of urban forests produce observed outcomes, in particular, urban forest benefits and costs. These human elements include the actors (people and groups) who interact with the urban forest, patterns of urban land ownership (e.g., whether urban forests are located on public or private property), and the management undertaken by these actors on different property types. Actors, ownership, and management impact the distribution of the benefits of urban forests as well as the direct costs of urban forests. The article concludes by presenting a comprehensive framework, synthesized from the literature, for understanding and studying urban forests as social-ecological systems.

Actors in the Urban Forest

The biophysical and ecological character of forests and trees in urban areas are extensively influenced by human actions. There are a number of different actors—individuals and groups—interacting in various capacities. The list of actors influencing the urban forest includes municipalities; privately-owned tree care companies; power companies managing utility rights-of-way; nonprofit organizations with missions connected to urban greening; residents’ or neighborhood associations; business associations; storm-water management districts; real estate developers and builders; property management companies; large institutional landowners (e.g., colleges and universities, hospitals, schools); homeowners, landowners, and other urban residents; and more. Each of these actors has a different jurisdiction and area of influence, as well as goals and capacities related to the urban forest. For instance, real estate developers looking to develop or redevelop single properties or large parcels of land may or may not value the urban forest as an important part of residential or commercial building projects, and they may or may not possess the skill, knowledge, or interest to design developments with infrastructure that promotes a healthy urban forest (e.g., by protecting large trees, preserving patches of existing forest, or designing adequate spaces for planting new trees). Utility companies manage trees along a utility corridor in which electricity infrastructure (power lines, etc.) is located; as such, utility foresters are concerned with maintaining the necessary clearance around power lines to as to avoid electrical service disruptions caused by trees.

Even within a single actor type, involvement with and capacity for urban forest management may vary across cities. For municipalities, resources (expertise, budget, etc.) available for urban forest management at the municipal level also impact the urban forest. In some cities, authority for urban forest and tree management is designated to the department of public works, while in others this authority may be held by parks and recreation, or in rare cases, a stand-alone urban forestry department. Some municipalities have certified arborists on staff—highly skilled, certified professionals trained in the care of trees—while other cities contract out tree work to private companies, or rely on untrained city staff to perform tree care (though the latter is not advisable). Additionally, the budget for municipal management of the urban forest can vary significantly from city to city, and some cities may even lack a dedicated urban forestry budget entirely, relegating urban forest management to crisis-response only (e.g., removal of hazardous trees, cleaning up debris from storms).

Actors may interact with one another on urban forest management. For instance, municipalities may be legally obligated to maintain the trees located along streets in the public right-of-way, but may contract the planting, maintenance, and/or removal of street trees to a private tree care company staffed by certified arborists or even to a local nonprofit organization that may in turn engage neighborhood residents as un-trained or semi-trained volunteer tree stewards in simple tree care tasks (e.g., watering recently-planted trees). Or, a local urban forestry nonprofit organization may collaborate with residents' associations and homeowners to plant trees in a new housing development with low canopy cover. Or stormwater management districts may collaborate with the local municipality on a tree giveaway program to encourage more planting of trees on private property.

Ownership: Public Versus Private Urban Trees

As alluded to above, different actors may be responsible—formally (legally) or informally—for taking care of different parts of the urban forest. The urban forest in cities is frequently described in terms of existing on either public property or private property (The concepts of ownership and property discussed in this section are biased towards Western European (colonial) ideas of private property. For better or worse, this is consistent with the majority of the urban forest discourses *writ large*. While the study of urban forestry in developing and non-Western countries is growing, future discourse and scholarship would benefit from being more inclusive of other land management regimes). *Public property* includes land owned or managed by a public entity, such as a municipality (village, town, city, or county government), public utility or other public authority (such as a state or national highway department), or the *public right-of-way* (area extending from the edge of a public street a certain distance onto adjacent private property, to which one or more public authorities have limited rights of access and use and sometimes also maintenance responsibilities over). Public trees include park trees and any additional trees on public land (a golf course, town square, publicly-managed cemetery, etc.), but also all trees in the public right-of-way (street trees, trees along a publicly-owned and managed trail, etc.).

Across an entire city, the public urban forest accounts for only a small percentage of the urban forest (though it should be noted that in some parts of a city, e.g., a city center business district, all of the urban forest may exist on public land or in the public right-of-way such as boulevards, parks, and public plazas). Private trees are the remainder of the urban forest not on public property, accounting for as much as an estimated 90% of “urban tree canopy cover” (the geographic extent of tree canopy covering an urban area, as measured through use of aerial or remote sensing imagery) (e.g., for Baltimore, MD, USA: [Troy et al., 2007](#)). This means that the vast majority of urban trees exist outside of direct public control or management, despite the fact that the benefits produced by the urban forest are largely benefits to the general public. And though a large scholarly discourse and practitioner community exist centered on municipal urban forest management (including even a specific certification for “Municipal Specialist” that supplements the International Society of Arboriculture [ISA] Certified Arborist credential; [ISA, 2019](#)), the portion of the urban forest existing on public land is minimal. Thus, collaboration among actors responsible for the public urban forest (i.e., municipal—staff and contracted—foresters and arborists) and those responsible for the private urban forest (e.g., individual homeowners, businesses, institutions with large tracts of land such as colleges, hospitals, etc.), is necessary for the urban forest as a whole to produce optimal benefits to all.

The Complexity of Urban Forest Management

All of these different actors all influencing urban forest outcomes in different ways creates a complicated and “polycentric” urban forest management situation. *Polycentric* refers to the many overlapping yet independent centers of decision making that exist in urban areas ([Ostrom et al., 1961](#): p. 831). Also called urban forest “governance” (e.g., [Lawrence et al., 2013](#); [Krajter Ostoić and Konijnendink van den Bosch, 2015](#)), this polycentric situation contributes to the sustainability and resilience of urban forests by creating redundancies in the management of urban forests: if one of these actors is unable to act on behalf of the urban forest (e.g., a recession causes municipal budget cuts that eliminate an entire urban forestry program or department), the others may be able to pick up the slack (e.g., adjacent homeowners may be able to pay for tree planting and maintenance in the public right-of-way).

Given this polycentric urban forest management, the specific level (or intensity) of management for a group of trees within the urban forest is connected to a number of factors, including whether the trees are planted or grew up spontaneously, what type of land use or property ownership the tree is growing on, and the party (or parties) responsible for or engaging in the management of the trees. The configuration of factors that impact urban forest management creates a gradient of management levels ([Fig. 1](#)),

Fig. 1 Examples of the types of trees and forests in and around urban areas, presented by where they likely exist along an urbanization and management gradient.

ranging from the completely unmanaged trees (e.g., such as those that have spontaneously grown up in vacant lots that are completely neglected by humans) to the most highly managed trees (e.g., street trees in narrow boulevards or tree pits adjacent high traffic streets, or in plazas in urban centers, where they need to be regularly watered, pruned, and monitored for pest/disease damage in order to maintain the appropriate and safe tree form). Fig. 1 shows how this gradient intersects with the urbanization (i.e., urban-to-rural) gradient for different types of forests.

The Distribution of Urban Forest Benefits across Urban Areas

The complexities of urban forest management in combination with the social and ecological heterogeneity of urban landscapes result in an unevenness of urban forest structure, which in turn creates disparities in who benefits from urban forests. Additionally, the people and groups who receive benefits from the urban forest may have different experiences of what those benefits are depending on how they interact with the urban forest and what their personal values, preferences, and experiences with nature are. This section describes these two issues and demonstrates that discussions of the benefits of trees are more complicated than just listing the many benefits and calculating an economic value.

Research has demonstrated that the urban forest is distributed unequally across urban areas. This results in environmental justice and equity issues since people are also not distributed equally across urban areas. Two recent meta-analyses (systematic, quantitative analyses of existing literature) have examined the relationship between urban tree canopy cover and income (Gerrish and Watkins, 2018) or race (Watkins and Gerrish, 2018), finding evidence for inequitable distribution of tree canopy by both demographic variables. Gerrish and Watkins (2018) synthesized 61 studies that researched the relationship between urban forests and income in urban areas and discovered that urban forests are inequitably distributed across income groups, with tree canopy cover (on both public and private lands) disproportionately lower in low-income areas. Watkins and Gerrish (2018) find a similar pattern for race: in their synthesis of 40 studies, they observe lower urban forest cover in areas of high minority populations (Watkins and Gerrish (2018) note that since low income and minority populations are often co-located in urban areas, the relationship between race and tree canopy cover is tightly connected to income, and thus recommend that any policies to address systemic inequities should consider both race- and income-based inequalities). They observe especially lower forest cover on public land in non-humid climates for African American residents (Watkins and Gerrish 2018). These findings have important implications for urban forest practice, particularly for efforts to address urban forest inequities. The actors engaged in urban forest management—including municipalities, nonprofit groups, professional urban foresters and arborists, and urban residents—have different responsibilities, capacities, and goals. For instance, research conducted in the Toronto, Canada, area by Conway et al. (2011) examined the urban forestry activities (e.g., conducting a tree inventory, planting or maintaining vegetation, stated importance of vegetation-related

issues) of business improvement associations and neighborhood residents' associations. Their findings suggest that residents' associations in particular engage in uneven levels of urban forest activities, leading to inequities in urban forest structure across neighborhoods that differ by racial, ethnic, and income characteristics (Conway et al., 2011).

Furthermore, urban forest benefits are experienced differentially by different people and groups within urban areas. Westphal (2003) developed a typology of understanding urban forest benefits—particularly social and economic benefits—that considers, on one dimension, whether benefits are accrued through passive experience of versus active involvement the urban forest and, on a second dimension, to whom the urban forest benefits accrue (on a scale of single individuals to an entire community). Westphal (2003) defines “passive experience” of the urban forest as simply being in the presence of urban trees, forests, and greenspace, while “active involvement” is defined as participation in an activity to green the urban environment such as planting trees or gardening. Fig. 2 maps select social and economic benefits of urban forests along these two dimensions. Both dimensions help answer the question of how urban forest benefits accrue to people. Some types of benefits are only experienced by those who actively engage with the urban forest. For instance, individuals who actively participate in tree planting, care, and management—either as professionals or as volunteer stewards of the urban forest—build skills associated with green trades. The benefit of skill building is only experienced by individuals engaged in active greening activities but not to the community at large. Another benefit that only results through active engagement is the stronger ties to other groups that organizations may experience as a byproduct of participation in collaborative urban forest management (e.g., city-wide tree planting initiatives). On the other hand, some benefits accrue to all people regardless of their level of engagement with the urban forest, simply due to the presence of trees. Individuals engaged in either active or passive forms of engagement with the urban forest may experience relaxed psychological states. The entire community benefits from a more pleasant urban environment due to the presence of trees.

A final issue in determining who benefits from the urban forest stems from the fact that the values of trees often calculated in tree benefits analyses (e.g., i-Tree or Tree Benefits Calculator, which produce a monetary figure for the economic benefit of the urban forest or single urban tree, respectively) are overly simplified. Valuations of the urban forest by necessity homogenize the preferences and values of people and groups in urban areas with respect to trees. In reality, the values of trees are heterogeneous not only across the spatial dimensions an urban landscape, but also across human communities. Different types of people, groups, and communities may value trees for different benefits. People's landscape preferences vary (e.g., a manicured lawn versus xeriscaped yard; trees and forests versus wide open spaces). The objectives of groups and organizations differ (e.g., a tree planting organization interested in planting large shade trees in a park that would produce lots of urban forest benefits versus an urban gardening group interested in planting only small fruit bearing trees and leaving sunny open spaces for gardening). Another example is the stormwater management benefits of trees and green infrastructure, which may be a primary concern for the municipal authority and stormwater utility coping with combined sewer overflows in a particular neighborhood; however, individual homeowners who do not experiencing flooding on their property may place a much higher value the shade and property value benefits of trees, or may even dislike trees due to needing to clean-up their leaves or because trees shade and reduce the efficacy of rooftop solar panels (see Opportunity costs in the section “The Costs of Urban Forests” below). Ultimately, the heterogeneity and complexity of urban environments and people complicate assessments of the benefits and value of urban trees and forests to human communities.

Fig. 2 The social and economic benefits of urban forests can be mapped along two dimensions: passive vs. active engagement with the urban forest; and, whether the benefit accrues on the level of a single individual to an entire community. Dimensions of social benefits of urban greening after Westphal, L. M. (2003). Social aspects of urban forestry: Urban greening and social benefits: A study of empowerment outcomes. *Journal of Arboriculture* 29(3), 137–147.

The Costs of Urban Forests

Another factor that complicates discussions of how urban forest management impacts urban forest benefits to people is that urban forests do not only have benefits; they also have substantial costs—both to individuals and groups, as well as to the public and the environment as a whole.

In order to understand how costs impact urban forest management and decision-making (and vice versa), it is helpful to review how urban forest professionals conceptualize tree benefits and costs in practice. Urban foresters often speak of trees and forests as one of the few types of physical infrastructure in urban areas that appreciate in value after installation, in contrast to the gray infrastructure such as streets, sidewalks, sewers, and other hardscape that begin depreciating the day they are completed. It is true that because trees grow after being planted in urban areas, a tree should theoretically provide an increasing level of benefits throughout its lifetime until being removed (Fig. 3). However, urban trees only appreciate if they are healthy and able to survive and grow to a large size where they provide substantial benefits. Research has found that if a cohort of trees (group of trees planted at the same time) do not survive at sufficiently high rates, the benefits produced by the cohort of trees does not increase over time—that is, the appreciation of benefits resulting from the growth of surviving trees does not outweigh the loss of benefits resulting from high tree mortality (Widney et al., 2016). Thus, for the benefits of the urban forest to increase over time, planted trees must survive. For planted urban trees, the establishment period—or the first 1–3 years after being transplanted, sometimes into a potentially harsh growing environment—can be a particularly vulnerable time where mortality rates are high. In order to survive and grow, planted trees must be cared for by people and, in particular, watered during the establishment period. Thus, though surviving trees do appreciate and provide benefits to people, they also require significant investment from people.

Investment, or maintenance costs incurred during a tree's early life, may be quite high (Fig. 3). Early costs include the costs of planting (purchasing high-quality tree stock from a nursery, plus labor and materials to put the tree in the ground, including tree workers, shovels for small trees or heavier equipment for large trees, any soil amendments used, mulch, water, etc.) as well as the costs of early essential maintenance for recently planted trees (watering during the first 2–3 growing seasons after planting, formative pruning to create appropriate tree form for urban areas, etc.). If a tree is optimally maintained early in life, the maintenance costs during the mature phase then go way down and are limited to occasional pruning, pest monitoring, and other types of routine mature tree maintenance.

For the urban forest as whole, there are two major categories of costs: “private costs” and “public costs” (Table 1; modified from a typology presented in Vogt et al., 2015b). *Private costs* are costs borne by a particular actor (group or individual) as part of expenditures on or because of the urban forest. Private costs include the direct costs incurred during management of the urban forest and costs resulting from tree conflicts (infrastructure repair and liability costs). *Public costs* are costs incurred because of the urban forest but not paid for by any particular actor and instead borne by society at large. Public costs include externality-related costs (also called ecosystem disservices) and opportunity costs. Direct costs, costs from tree conflicts, liability costs, and opportunity costs are discussed in greater detail below.

Direct Costs—Management and Maintenance

Direct costs incurred during the provisioning and maintaining of trees and the urban forest are private costs. These costs—i.e., management costs—include expenditures on labor and materials required to plant trees (the trees, tools, mulch, soil amendments, water and water equipment, etc.). Direct costs are paid by actors performing specific actions in order to manage the urban forests, for

Fig. 3 Generalized (hypothetical) profile of the annual benefits provided by and costs incurred from over the entire lifetime of a single tree from planting to removal. The net benefits provided over the entire tree's life can be conceptualized as the area in between the benefits (solid line) and costs (dashed line). Modified from Vogt, J. M., and Fischer, B. C. (2014). A protocol for citizen science monitoring of recently-planted urban trees. *Cities and the Environment* 7(2), art. 4. Available at: <http://digitalcommons.lmu.edu/cate/vol7/iss2/4> and Vogt, J., Hauer, R. J., and Fischer, B. C. (2015b). The costs of maintaining and not maintaining the urban forest: A review of the urban forestry and arboriculture literature. *Arboriculture & Urban Forestry* 41(6), 293–323.

Table 1 Types of costs associated with urban forests.

	Type of cost	Explanation/examples
Private costs	Direct costs (i.e., maintenance and management costs)	Dollars expended to purchase labor and materials involved in the planting, pruning, watering, and other types of maintenance of trees in the urban forest
	Infrastructure interference costs (i.e., repair costs)	Pavement and sewer repair costs; removal of tree limbs or debris blocking signage, power lines, storm drains, etc.; costs from tree-initiated power outages; or other costs incurred when trees damage or interfere with infrastructure
	Liability costs	Damages paid from a lawsuit or settlement awarded when trees or parts of trees cause injury to persons or property, such as an improperly cared for tree falling on a house, vehicle, or person
Public costs	Externality-related costs (aka, “ecosystem disservices”)	Emissions of biogenic volatile organic compounds (VOCs) by trees; allergies due to tree pollen; release of carbon dioxide during decomposition of trees or tree debris or by maintenance equipment (gas-powered chain saws, lift trucks used to access tree canopy during maintenance, etc.); leaf/debris clean-up
	Opportunity costs	Space where trees are planted cannot be allocated to other competing uses, such as parking, bike lanes, sidewalk cafés, etc.; shade from trees may preclude use of sunny areas for installation of solar panels or for gardening

Modified from Vogt, J., Hauer, R.J., and Fischer, B.C. (2015b). The costs of maintaining and not maintaining the urban forest: A review of the urban forestry and arboriculture literature. *Arboriculture & Urban Forestry* 41(6), 293–323.

instance, municipal budget outlays for the pruning of street trees. In order to better understand the magnitude of the direct costs of urban forests, it is helpful to understand the types of maintenance required by urban trees and forests, and how maintenance and management impact urban forest outcomes.

A note on terminology: The terms “maintenance” and “management” are often used interchangeably with respect to the urban forest, though they mean slightly different things. For the purposes of the following discussion, *maintenance* will refer to activities undertaken with the intent of caring for individual trees, while *management* will refer to activities to care for urban trees in the aggregate (so, maintenance of trees, but management of the urban forest).

There are a number of activities commonly undertaken to maintain urban trees, including transplanting, various types of pruning (e.g., formative pruning of young trees and structural pruning of mature trees to create appropriate form for urban spaces, pruning to remove dead or broken branches after storms); watering (during establishment after transplanting, or during periods of drought); mulching (ideally, seasonally, to hold in soil moisture and minimize competition between tree roots and grass, weeds, and other plants); amending soils (if needed, through fertilization or inoculation with mycorrhizae), inspecting and treating for pests and diseases (also called “plant health care”), installing tree support or lightning protection systems (generally only for old, mature, or particularly significant trees), and, finally, removing trees and tree stumps (either due to conflict with other infrastructure, during construction, as a result of natural or pest/disease-related mortality, etc.).

The cost of the labor and materials necessary to performing these maintenance tasks may be paid for by one or more actors in the urban forest: municipal urban forestry programs; individual homeowners, business-owners, or institutional landowners maintaining trees on private property; nonprofit urban forestry organizations; or any other party taking fiscal responsibility for the maintenance of public or private trees. The data that exists on the relative costs of different types of tree maintenance activities is limited (Vogt et al., 2015b), but a recently conducted census of municipal tree care activities in the United States revealed that tree pruning and tree removal are the costliest tree care expenditures as a percent of total municipal urban forestry budget (Hauer and Peterson, 2016). Fig. 4 shows the relative costs of other specific maintenance and management activities included in municipal tree care (from Hauer and Peterson, 2016).

One of the ways trees are maintained is by being planted in cities in the first place. However, researchers have estimated that only approximately one-third of trees in North American cities are planted (Nowak, 2012), leaving a substantial number of trees within urban areas that emerge spontaneously. This spontaneous tree generation has led to a significant invasive species problem for some cities. For instance, in Chicago area, it has been estimated that over one-quarter (28.2%) of the trees in the region (by count) are the invasive European buckthorn (Nowak et al., 2013). Since buckthorn is a small-stature species that does not provide a large number of benefits, this can yield substantial pressure on urban forest managers to remove this and other invasive species in the urban forest, particularly in the more naturalized, less highly managed areas of the urban forest where buckthorn may compromise the quality and integrity of urban forest ecosystems.

Fig. 4 The average percent of municipal urban forestry program budgets spent on particular tree maintenance and management activities, based on a 2014 survey of municipal urban forestry programs in the United States. An * indicates an activity that is management, while other activities are maintenance. Data used with permission from Hauer, R., and Peterson, W. (2016). *Municipal Tree Care and Management in the United States: A 2014 Urban & Community Forestry Census of Tree Activities*. 16–1. Stevens Point, WI. Available at: <https://www.uwsp.edu/cnr/Pages/Forestry—MTCUS.aspx>.

In examining how maintenance impact urban forest outcomes, the language of ecologists when discussing the impact of ecological disturbances (cf., Walker and Willig, 1999) is useful. Urban forest structure is influenced not only by the type of maintenance, but also the party performing the maintenance as well as intensity (how much maintenance is performed), frequency (how often maintenance is performed), duration (for how long maintenance is performed), and extent (on what part of a tree, or which trees within the urban forest). Just like when considered for ecological disturbances are called a “disturbance regime” (e.g., Hobbs and Hueneke, 1992), these factors together make up a “maintenance regime,” which impacts the structure of each urban tree individually as well as the urban forest in the aggregate.

In addition to the maintenance performed on urban trees, additional urban forest management activities are also part of the direct costs of urban forests. Management activities consider the entire urban forest—or a significant aggregation of trees such as those in a park or park system, all the trees in a neighborhood or along a corridor, etc.—and generally involve higher-level planning, advocacy, and even policy-making activities. This includes urban tree inventory and analysis, generating master and strategic plans for the urban forest, engaging in public education, outreach, and awareness building, lobbying for or creating tree policy at the municipal or even state or national level, plus the generic administrative and office expenses of running any type of program. These costs are more likely paid for by groups engaging in stewardship of the urban forest for a city such as municipal urban forestry programs or urban greening nonprofits, rather than by particular individuals such as homeowners. However, large private or institutional landholders such as colleges and universities, or neighborhood/residents’ associations or business associations may also engage in management activities that have costs.

Costs Resulting from Tree Conflicts—Infrastructure Repair and Liability Costs

In addition to the direct costs of urban forest maintenance and management, there are also private costs that result from tree conflicts in the urban environment including infrastructure interference and liability costs. Infrastructure repair costs are incurred due to above- and belowground conflicts. Above ground conflicts include tree branches growing into fences, signage, or—most commonly—above ground power and cable lines. In particular and most costly, when trees sufficiently conflict with power lines such as during or after a storm or high-wind event, they can cause power outages that result in costly tree debris cleanup and power infrastructure repair, as well as loss of revenue to the power company for the duration of the service outages. Belowground conflicts result when tree roots grow into storm sewer drains or water supply pipes or underneath sidewalks or curbs causing buckling of the concrete. The cost of repairing damaged infrastructure are generally paid by the actor responsible for management of the infrastructure needing repair (electric utility companies, water management authorities, or public works departments managing streets and sidewalks).

In almost all cases, conflict between trees and infrastructure results from improperly planted and/or maintained trees, not from inherent or unavoidable tendency for trees to cause damage. For instance, it is a common misconception that tree roots will always interfere with a storm sewer or water supply pipe if the two share the same underground space. However, in reality existing small cracks or inadequately sealed joints in aging pipes leak moisture or nutrients that attract small tree roots, which then expand small cracks into large cracks or roots grow into the pipes contributing to clogs. Similarly, a tree with a large mature size planted under a power line will become an interference, while a tree with a small mature size planted in the same place will cause no problems with above ground power infrastructure. This is why there is a popular maxim among urban foresters: “right tree, right place, right time,” meaning that when planting trees, urban foresters must consider the proper tree (species, size at maturity, etc.) for the proper place (planting area type, soil and environmental quality, etc.) and plant the tree at the right time (at the right time of year for seasonal climate, or after a major construction project not before, etc.).

In the worst cases, improperly planted and maintained trees can cause serious damage to property or injury to people. If the person whose property or person is injured decides to pursue legal remedy, a lawsuit can result in the assigning of liability for the tree causing injury and paying of monetary damages to the victim. Thus, liability costs are incurred and paid as legal settlements by the actor taking responsibility for (or deemed responsible in a court of law) the tree that caused the damage. In the case of trees on private property, this is usually the property owner, but for trees in the public right-of-way, assigning legal responsibility for the damage caused by the tree can get more complicated. For instance, the physical land in the right-of-way is owned by the adjacent property owner but the city generally has access rights for certain purposes such as maintaining the sidewalk or accessing buried sewer pipes. Responsibility for mowing the grass or maintaining any non-tree vegetation in the right-of-way boulevard between the street and the sidewalk may fall to the adjacent homeowner, yet legal responsibility for planting, maintaining, and removing any trees in the right-of-way may be either held by the city or may also be the duty of the adjacent homeowner. If legal responsibility over a tree is unclear due to the lack of clear delegation of responsibility of tree care and maintenance or lack of clear ownership of the property on which the tree itself is located, who has liability for the tree in the event of partial or entire tree failure is murky and will need to be determined in a court of law. Whoever is liable for the tree will then be responsible for paying any monetary damages awarded to the victim. Municipalities that take responsibility over the trees in the public right-of-way may even budget for paying liability claims (in or out of court), although it is obviously preferable for any party in charge of part of the urban forest to monitor and maintain trees in order to proactively assess tree risk and avoid any tree failures that cause injury to persons or property.

Opportunity Costs—A Public Cost of Urban Forests

The private costs described above—maintenance and costs resulting from tree conflicts—are paid for by someone. The public costs of urban trees and forests, on the other hand, are those costs borne by no particular individual or group but instead by urban residents as a whole. These include ecosystem disservices and “opportunity costs.” Ecosystem disservices are the negative externalities produced by urban trees and forests, such as pollen that causes allergies. *Opportunity costs* are the costs of undertaking one particular action or decision and foregoing another. In the context of urban trees and forests, opportunity costs refer to the activities or land uses that cannot be engaged in if urban trees and forests are planted, managed, etc. For instance, there is limited space in the public right-of-way and many competing possible uses for this space such as parking, bicycle lanes, sidewalks, a grassy boulevard, bench, bike racks, waste receptacle, sidewalk café, raised flower bed, trees, etc. Since not all of these uses can happen simultaneously, whenever one particular use is chosen for a given space, the cost of forgoing the other types of uses for the space is considered the opportunity cost of a particular use. If trees are planted in the public right-of-way, the space cannot be used for a sidewalk café by an adjacent restaurant. On other types of public land such as parks or public squares, opportunity costs are similar: for instance, if there is a forested area in a portion of a park, this area cannot be used for a parking lot, picnic area, public pool, or other use. The opportunity costs of trees are not just relevant on public lands. Private landowners can face opportunity costs as well. Trees that cast too much shade may preclude installation of solar panels on the roof or use of a yard space for gardening of vegetables that require sunlight.

Urban Forest Sustainability

Whatever the configuration of individual trees and patches of forest and actors managing the urban forest, in the end, when the costs of urban forests are subtracted from the benefits—either as a formal, mathematical calculation, or an informal comparison of the benefits and costs—ideally, net benefits are positive. And in the optimal scenario, the net benefits of the urban forest are not just positive at a given point in time, but they are sustained (or increase) over time.

What Does “Sustainability” Mean for Urban Forests?

There are two different angles from which scientists and practitioners have conceptualized sustainability as related to the urban forest. The first and most common way of conceptualizing urban forest sustainability considers primarily the persistence of the urban forest resource itself—that is, the trees—over time, and thus, by proxy, the net benefits provided by the urban forest in the

Fig. 5 Two different ways of conceptualizing urban forest sustainability: (A) As an approximately sustained level of a particular urban forest structural parameter such as canopy cover (or level of net benefits) over time; or, (B) As part of meeting human needs while making sure that Earth's environmental limits are not exceeded. (B) After Raworth, K. (2017). *Doughnut economics: 7 ways to think like a 21st century economist*. White River Junction, Vermont: Chelsea Green Publishing, as adapted for urban forests by Vogt, J., and Hauer, R. (2017). Sustainability science for urban foresters and arborists. *Arborist News* 26(4), 28–34.

aggregate. A “sustainable urban forest” in this context refers to maintaining an approximately consistent level (or increasing level) of a particular structural parameter such as canopy cover, stocking level or number of trees (Fig. 5A), or of the urban forest benefits provided (cf. Clark et al., 1997; Dwyer et al., 2003). Because of the way tree structure is connected to function and benefits, the largest trees in the urban forest provide the most benefits and since tree mortality is highest for planted trees during the establishment period just after transplanting, sustaining an optimized level of urban forest benefits through time involves maintaining a diverse species assemblage and appropriate distribution of trees of different sizes and ages (Fig. 6; after Richards, 1983).

The second way to conceptualize urban forest sustainability involves a more holistic assessment of how urban forests might fit into larger efforts for community or urban sustainability (or even global sustainability). In this context, sustainability is defined as meeting human needs (food, housing, energy needs, etc.) while making sure that the environmental limits of the Earth (for processes such as climate change, freshwater use, land system change, etc.) are not exceeded (cf., the definition of sustainability used by Steffen et al. (2015) and Raworth (2017)) (Fig. 5B). So the quest for the sustainable urban forest then is how can urban forests contribute to meeting human needs without exceeding Earth's environmental limits (cf., Vogt and Hauer, 2017)? For instance, in hot dry climates, properly placed drought-tolerant trees can provide shade and decrease urban temperatures help mitigate the impacts of climate change without requiring excessive amounts of freshwater for irrigation. Another example is the planting of fruit trees, which provide fresh food in urban food deserts and contribute to meeting human needs.

These two conceptualizations of urban forest sustainability are not necessarily incompatible. The former (Fig. 5A) is a much more specific idea of what sustainability of the urban forest is and to be satisfied requires only that the urban forest (i.e., the trees as a natural resource) be maintained. The latter (Fig. 5B) requires consideration of multiple urban forest benefits and costs in the context of the trade-offs between environmental- and human-related sustainability goals, which can contribute to the maintenance of the urban forest (that is, the persistence of urban forest structure over time, as in Fig. 5A). Depending on the existing urban forest situation (structure, actors, etc.), one or the other means of operationalizing sustainability may be more desirable.

Fig. 6 Size class distribution of trees in an urban forest that sustains a constant level of net benefits over time. Figure created from a text description of the appropriate “age distribution”—where tree size is a proxy for age—for a “stable” urban forest, as described in Richards, N. A. (1983). Diversity and stability in a street tree population. *Urban Ecology* 7(2), 159–171.

Table 2 Components and criteria of a sustainable urban forest. Optimal performance levels, as well as the key objective that performance level is designated to achieve as defined by Kenney et al. (2011) are shown. Performance levels for each criteria can be found in the Appendix of Kenney et al. (2011).

Component	Criteria
Vegetative resource	Relative canopy cover
	Age distribution of trees in the community
	Species suitability
	Species distribution
	Condition of publicly owned trees
	Publicly owned natural areas
	Native vegetation
Community support	Public agency cooperation
	Involvement of large private and institutional land holders
	Green industry cooperation
	Neighborhood action
	Citizen-municipality-business interaction
	General awareness of trees as a community resources
Resource management	Regional cooperation
	Tree inventory
	Canopy cover inventory
	Citywide management plan
	Municipality-wide funding
	City staffing
	Tree establishment planning and implementation
	Tree habitat suitability
	Maintenance of publicly owned, intensively managed trees
	Tree risk management
	Tree protection policy development and enforcement
	Publicly owned natural areas management planning and implementation

Components and criteria listed from: Clark, J. R., Matheny, N. P., Cross, G., and Wake, V. (1997). A model of urban forest sustainability. *Journal of Arboriculture* 23(1), 17–30.

Criteria for Evaluating Urban Forest Sustainability

Within the field of urban forestry one of the first to consider urban forest sustainability was Clark et al. (1997), who presented an approach for evaluating urban forest sustainability. They consider the characteristics of the urban forest and urban forestry activity within a single municipality that are crucial to sustaining the urban forest resource over time. For these authors, a “sustainable urban forest” refers to an urban forest system that persists “over time in a way that provides maximum benefits from the functioning of that forest” (Clark et al., 1997: p. 17). To this end, they describe the three core components of a sustainable urban forest—a healthy vegetative resource, comprehensive management, and a supportive community—as well as a set of criteria that if achieved should yield a sustainable level of urban forest benefits over time (Clark et al., 1997; Table 2). The framework was updated and clarified by Kenney et al. (2011), who added detailed performance indicators to each of the criteria in the Clark et al. (1997) three core components, in order that managers or others might actually measure the sustainability of a particular urban forest according to the framework by assessing the level of performance for each of the sustainability criteria.

What Shapes Urban Forest as Social-Ecological Systems?

As illustrated in this chapter, a confluence of complex factors shape the trees and forests in urban areas. Observed characteristics of urban forests—such as urban forest structure, benefits, ecosystem disservices, and sustainability—are ultimately shaped by both human and biophysical factors. Because of this urban forest ecosystems can be best understood as “social-ecological systems.” A *system* is a group of components interacting in a self-organizing capacity to generate some type of outcome or function that would not be intuitive based on the sum of the components. More simply, systems are “a set of things ... interconnected in such a way that they produce their own pattern of behavior over time” (Meadows, 2008). *Social-ecological systems*—sometimes also called “socio-environmental systems” or “coupled human-natural systems”—are systems of both human and natural subsystems, where the inter-workings of each subsystem are inseparable from one another and the entire system cannot be fully understood without looking at the system as a whole (c.f., Ostrom, 2009; Epstein et al., 2013; Vogt et al., 2015a). Urban forests—with their interlinked

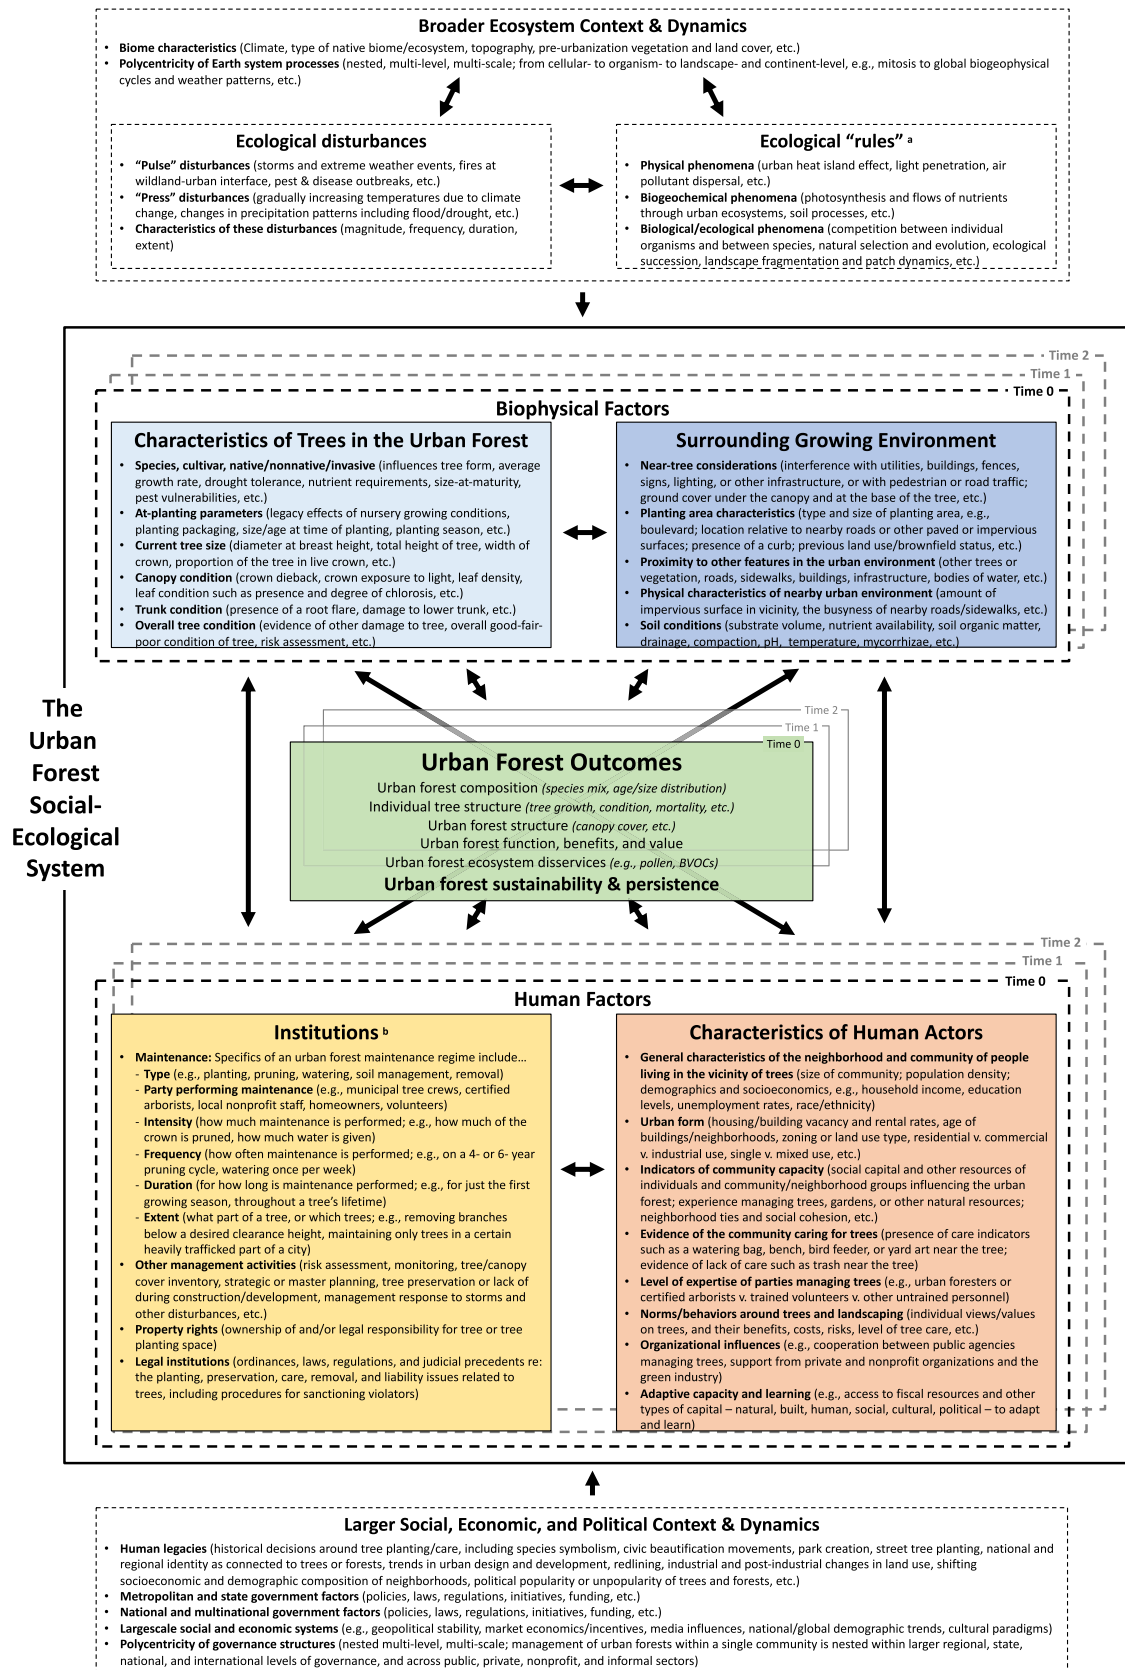

Fig. 7 A comprehensive framework for understanding and examining observed outcomes in urban forests as social-ecological systems. There are four core sets of endogenous variables relating to characteristics of the tree, the surrounding growing environment, institutions, and the characteristics of the human community, which interact to produce observed urban forest outcomes. Core sets of variables, interactions, and observed outcomes are dynamic and may change over time. Additionally, core sets of variables are influenced by the context and dynamics of the

systems of trees and the people and groups who interact with those trees to produce the character of the urban forest—are social-ecological systems (Vogt and Fischer, 2014; Vogt et al., 2015c).

In seeking to understand how any system functions, it is often of interest to examine the sets of components within the system and the relationships between components, in order to elucidate how interactions lead to observed outcomes. A framework is useful to this end. A framework contains general sets of variables that may be related to one another in order to “[provide] a metatheoretical language to enable scholars to discuss any particular theory or to compare theories” (Ostrom, 2010). Frameworks can be particularly useful for fields such as urban forestry that are *transdisciplinary*—that is, that combine knowledge and methods from multiple academic disciplines and from research and practice and integrate both researchers as well as non-researcher stakeholders from across multiple sectors—and can help provide a common language for communicating.

For urban forests, a comprehensive framework for understanding and examining urban forests as social-ecological systems is presented in Fig. 7 (based on an unpublished manuscript-in-progress by the author; synthesized from existing urban forestry frameworks by Clark et al. (1997), Mincey et al. (2013), Vogt and Fischer (2014), Vogt et al. (2015b,c), Steenberg et al. (2016), Roman et al. (2018), and Hilbert et al. (2019); and the social-ecological systems framework by Ostrom (2009); as updated by Epstein et al. (2013) and Vogt et al. (2015a)). In the framework, the factors that shape urban forest outcomes are numerous, but can be broadly grouped into four core sets of variables: the characteristics of the tree; the surrounding growing environment; *institutions* (the rules and strategies governing interactions between humans and between humans and the environment, in this case, the maintenance and management of the urban forest); and the characteristics of the human community. These core sets of variables interact with one another, but are also influenced by broader ecosystem dynamics, as well as the larger social, economic, and political systems within which urban forests exist. All of these factors must be considered in order understand the complex outcomes observed in urban forest ecosystems and in efforts to study urban forest dynamics.

Conclusion

Urban forests are all the trees and vegetation existing in close concert with humans in some of the most densely settled places on the planet. As such, in order to understand the biophysical and ecological character of urban forests, we must examine how the various actors, from professional urban foresters to homeowners to urban greening nonprofits, maintain and manage the urban forest on both public and private property. This management (or, sometimes, such as on vacant lots, lack thereof) results in urban forest benefits or ecosystem services (such as aesthetic beauty, shade, and stormwater management). But trees, forests, and the management they require also has costs, including direct, private costs for maintenance (such as pruning, watering) or to deal with tree conflict with infrastructure (e.g., heaving up sidewalks), as well as public costs in the form of ecosystem disservices (e.g., tree pollen producing allergies) and opportunity costs (space for trees in the public right-of-way cannot also be used for a bike lane). Because of these interactions between humans and the vegetation in cities, the urban forest can be best understood as a social-ecological system.

broader ecosystem and social, economic, and political systems within which urban forest exist. ^a“Ecological rules” language after Epstein et al. (2013) and Vogt et al. (2015a). ^b“Institutions” refers to the formal and informal rules and strategies that structure interactions between people and between people and the environment, after Ostrom (2005). Abstract

This article posits the idea that while the idea of an anthrome may be relatively new, several cities of the global south with histories of settlement spanning several millennia are indeed examples of long standing anthromes. They have been shaped by and in turn influence human society creating a co-evolved, tightly coupled social ecological system. Using the case of the waterscape within the south Indian city of Bangalore, we demonstrate how nature and society have shaped, transformed, and influenced each other's trajectories of development over several millennia. These coupled with today's conditions of uncertainty caused by the Anthropocene, have created unique challenges of equity, justice, and sustainability—all of which need to be considered in the new age urban planning discourse.

A Peopled Planet

We live in the era proposed as the Anthropocene—an era synonymous with the pervasiveness of the human footprint. An era where human actions and behavior have not just shaped societies and cultures, but also transformed the non-human and non-living components of the biosphere. Cities are examples of such transformations—they are landscapes that are constantly increasing in number, and evolving to represent predominant trends in economies, lifestyles, and associated global connections. Over 55% of the global population today live in cities, with that number projected to reach about 75% by 2050. Given the dense concentration of people in cities, it is only expected that these spaces be modified, transformed, and shaped to represent the greatest utility to people who live there.

Cities are social-ecological systems—with complex coupled interlinkages between people and nature, influenced and being influenced by each other. Thus contemporary expressions of the urban space are essentially productions of complex interactions between people and nature—both those which have occurred in the city's past, and are ongoing in various forms today. Not surprisingly, then cities also represent “novel ecosystems”—ecosystems that have been significantly altered and reshaped in structure and process by human influence, and that are further managed in ways that espouse specific human purposes. Further, the reach and pervasiveness of human influence within these ecosystems means that local ecologies and biodiversity become altered in ways and abundances that were not originally a part of the landscape. For example, the creation of agrarian landscapes and their transformations (such as the example of Bangalore that follows), were sustained through the creation of novel ecosystems characterized by populating barren land or replacing native vegetation with domesticated plant or animal species in order to further human life and productivity. These transitions and associated creation of novel ecosystems relate explicitly to the idea of the Anthropocene—the new proposed geological epoch characterized by rapid changes in global social-ecological conditions that have been brought about primarily by the scale and reach of human activity on the planet. Within urban settings, these transitions into novel ecosystems may have occurred across long time scales, governed by multiple resource regimes (each with their own priorities and urban visions), interacting with each other and building upon prior regimes, it is highly unlikely that one can envision a future that returns these ecosystems to their original form and function. Urban ecosystems thus have to be managed bearing in mind their unique historical trajectory of transformation in form, function and imagination, and with attention to the social and ecological roles they play in the contemporary and future city.

The south Indian city of Bangalore represents a classic example of these novel ecosystems. Old inscriptional records attest to the pervasive role that humans have played in shaping and modifying the social-ecological systems in the landscape surrounding Bengaluru, from as far back as the 6th century CE. This is especially visible when one focuses upon transformation of urban commons—lakes, village forests, village pastures and other ecosystems—across regimes of governance imposed by successive dynasties of the precolonial era (before CE 1799), the British colonial regime (CE 1799–1947) and the modern Indian independent state (CE 1947–present). Conceptualized and built to support a predominantly agrarian lifestyle, the lakes, orchards and pastures created by village communities have transformed the landscape, and co-evolved with the growth of human settlements over multiple centuries. In this article, we provide a detailed account of these transformations, making the case for this city as a novel ecosystem that gives us a deep insight into processes of urbanization in parts of the global south, that are rapidly urbanizing yet continue to represent a major knowledge gap in research on Anthromes.

Setting the Context: Bangalore

Bangalore, once called India's "Garden City," was well known for its green spaces and its pleasant weather, owing to its location on the elevated Deccan Plateau. In recent years, it has become synonymous with the outsourcing of the global information technology industry, becoming called the "Silicon Valley of India." Bangalore has since colonial times been a strong player in the global scenario, because of its strategic location for colonial civil and military establishments, and its continued economic importance within independent India. The colonial state of Mysore (of which Bangalore was a part) was a site of experimentation with modernity, thus making Bangalore one of the first cities in India to receive electricity, telephone connections and centralized piped water and sewerage networks. In part, these innovations fuelled the rapid urban growth of the city, attracting greater densities of people, paving the way for its current-day reputation as one of independent India's major metropolitan cities.

At the same time, Bangalore has also had a trajectory of dramatic landscape transformation as evidenced by its blue and green infrastructure. Geographically, the city lies in the rain shadow of the Deccan Hills, and as such lacks a major perennial water source, making it prone to aridity and drought. Despite the constant challenges of water availability, the city has been occupied since prehistoric times, and has been inhabited by settlements since at least the 6th century CE. The expansion of human settlement in this landscape is owed in part to the creation of networked reservoirs designed to capture and harness rainwater across the elevation gradient characterizing the city. Designed for meeting the needs of the primarily agrarian precolonial societies, these reservoirs (tanks or lakes as they are known today) operated in tandem with a selection of other urban commons including village forests, cemeteries, temple tanks, and large open wells (that tapped into shallow aquifers recharged by the tanks). Today, however, several of these commons have disappeared from the cityscape, or have been repurposed for meeting other urban demands (such as those of residential space or public infrastructure), while the remaining ones are rendered vulnerable by pollution, encroachments, and general neglect (Fig. 1).

The two main uses for which this system was engineered have either disappeared or taken on new forms—the former, which is now restricted to small urban pockets, and the latter, which is obtained through a system of long distance transfer—rendering the social fabric upon which the system operated redundant. At the same time, these spaces, the urban commons, continue to perform valuable ecosystem services (such as attracting local biodiversity, regulating the urban microclimate, and groundwater recharge among others), that make them ecologically indispensable. Urban commons within these contexts refer to (formerly) collectively managed resources such as lakes and associated village forests, grazing lands, and other spaces. They also represent spaces from which it is difficult to exclude people from while at the same time the total amount of available resources decreases, the more benefits are extracted from them. They thus represent both integral yet highly vulnerable ecosystem resources within cities.

As such the story of these spaces represent both the creation and co-evolution of a novel ecosystem as well as illustrates the challenges involved in their governance and management. In the following sections, we will attempt to trace the coevolution of Bangalore's urban commons through processes of urbanization from precolonial times to the present. In doing so, we will also demonstrate how through centuries of anthropogenic transformation, the city represents a "novel ecosystem" that encapsulates and presents multiple, power laden, conflicting visions and thus associated challenges for ecosystem management.

Engineering Flows of Water and Culture—Bangalore's Precolonial History

The earliest records available for the landscape around the contemporary boundaries of the city of Bangalore are in the form of copper plate and stone inscriptions (that date back to about the 6th century CE). These provide a record of the presence of varying local chieftains and rulers. They describe various events such as the grant of land, battles, the creation of lakes, and the grants of revenues from agriculture to temples. Inscriptional records also provide valuable insight into the geophysical landscape of the time, both in terms of their content as well as in terms of their chronology and spatial locations.

Geographically, Bangalore consists of both elevated regions (known locally as *malnad*) as well as plains (known locally as *maidan*). Our research has shown that settlements in this city spread from the plains (where the earliest inscriptions have been found) to the hills. In order to support agriculture, early settlers made use of the natural elevation gradient and undulating terrain to build reservoirs to harvest rain water. Connected by means of channels, and designed to harness rainwater, a system was created whereby water overflowed from one reservoir into the other, providing water to the city. The building of these tanks continued for

Fig. 1 (A) Map showing the distribution of lakes in colonial Bangalore—CE 1885. (B) Map showing the distribution of lakes within the formerly colonial spread of Bangalore city—2014. *Note:* Both of these figures were previously published in an Arcadia article by the authors titled “The lost lakes of Bangalore,” available at <http://www.environmentandsociety.org/arcadia/lost-lakes-bangalore>. several centuries, supported by local residents, communities and chieftains owing allegiance to multiple regional dynasties. Along with these seasonal surface water sources, people made use of open wells associated with each lake as a secondary source of water, ensuring water availability throughout the year. Open wells drew on groundwater in shallow aquifers that were recharged by the tanks.

By re-engineering the waterscape, this process of tank building irreversibly transformed a semi-arid landscape devoid of trees into a fertile landscape conducive for agriculture, horticulture, fishing and grazing. Over the centuries, the city transformed into a space that not just provided for agrarian livelihoods, but also into a rich biodiverse landscape with forests and wooded groves, populated by wildlife and birds—in other words, an engineered urban commons. British colonial interventions continued to shape this novel

ecosystem, via technological and engineering interventions to the city's waterscape that reshaped human activities and livelihoods centered around these ecosystems.

Engineering Modernity: The Colonial Tryst With Bangalore

The advent of colonial rule in India and more specifically into the city of Bangalore (starting at the end of the 18th century) brought transformative changes to the landscape. These changes had impacted people and biodiversity, and were driven in part by rapidly changing demographics of the city, notions of health, hygiene and sanitation, advent of technology that enabled modernization of infrastructure, leading to associated changes in the meanings ascribed to resources formerly important for utilitarian purposes, as well as a form of urban planning that was reflective of these important transitions.

Colonization and Changing Demographics of Bangalore City

Bangalore, as noted earlier, was particularly well placed to support the colonial enterprise not least because of its high elevation and resulting mild weather conditions. This attractiveness of the city drew large numbers of European settlers, so much so that by the middle of the 19th century, Bangalore was being referred to as the "Pensioner's Paradise." It was also a very strategic place within the Deccan plateau for the setting up of one of many British Cantonments in south India. In addition to attracting large European populations, these events also attracted large numbers of native migrant populations in search of labor from neighboring towns and states. This influx of people meant increased requirement of land and water to meet the requirements of the population. On the one hand, between the late 1880s and until the country became independent in 1947, this demand for land meant the creation of several new residential extensions and public infrastructure such roads, railways, and recreational amenities. Several of these new settlements were facilitated by repurposing existing water infrastructure—the rain water channels and lakes.

The increased demand for water also came at a time when the city received electricity, and began to be supplied by a networked and piped water supply systems connecting every household. Beginning from the late 19th century, water began to be pumped from increasingly longer distances outside the city, settling finally upon the river Cauvery over a 100 km upstream of the city. The formerly important tank system, now unable to meet the needs of an expanding population (among other factors) fell into gradual disuse, or became repurposed in various ways—converted into buildings, drained for use as playgrounds, parks and exhibition grounds, and used to store waste and sewage.

Colonial Notions of Health, Hygiene, and Sanitation

An increase in population was not the only factor that brought about transformations within this waterscape. The advent of colonialism into the city also brought with it lived experiences of the Europeans with epidemics such as bubonic plague and malaria, both within their native homelands as well as within the colonies they established. These experiences shaped the creation, reproduction, and perpetuation of discourses on what constituted healthy and hygienic urban spaces. European experiences with the prevention and control of disease in one part of the world (such as bubonic plague in England, or plague, malaria and cholera in India) were further transplanted into other parts of the Empire, reacting and often conflicting with local social and ecological contexts, producing distinctive cityscapes.

It was in India that the idea of racially segregated zonation of urban centers was developed, ostensibly to keep British soldiers free from diseases (e.g., cholera, plague, malaria, and typhoid), perceived as prevalent in designated "native towns." The British Raj created the institution of British Cantonments—military outposts in several Indian towns, that were physically separated from the native city. The Cantonment in Bangalore, which operated between 1798 and 1947 was one of the largest and most prominent.

Bangalore served as an example for the larger colonial enterprise in terms of experimenting with infrastructure and town planning (the city for instance pioneered networked water infrastructure projects and was also the first city to receive electricity in South Asia). For the 1902 Nobel Laureate, Sir Ronald Ross, then stationed in Bangalore as a Surgeon Major, the city became an experimental site for his path-breaking work on malaria. Further, Ross's encounters with epidemics of cholera, plague, and typhoid in Bangalore, led him to propose and influence the implementation of centralized, networked systems of sanitation, conservancy, and water supply to increase health and life expectancy. The model of town planning that emerged from these experiments emerged as the signature of British colonial establishments across the global south, indeed forming the foundation upon which infrastructure and urban planning in these cities continue to rest upon.

What did these ideas mean for the tank infrastructure that was characteristic of this town? First, the idea of a water resource began to shift from collectively managed, open reservoirs to those contained within hygienic, enclosed spaces. This necessitated the construction of enclosed, covered reservoirs, into which water would be pumped in by an equally enclosed, reticulate system of pipes. Concomitantly, open reservoirs (such as tanks and their associated channels) began to be perceived as unhygienic and therefore carriers of disease, filth, and other hazards. People dependent upon such reservoirs (such as native communities of washer folk—the *dhobies* as they were locally known, farmers, and fishermen) began to be perceived also as being unsanitary and prone to disease. People were on the one hand actively discouraged from depending upon these formerly important infrastructure, and on the other, the idea of racial segregation between European and native populations was perpetuated along lines of health and

hygiene. The tanks, in keeping with this line of thinking, began to be seen as conduits for the city's sewage—transforming what was essentially a seasonal fresh water resource designed to capture rainwater, into perennial bodies associated with the city's refuse. These ideas further accelerated the decline and conversion of Bangalore's many water bodies and associated channels, rendering them polluted, and thus allowing them to be repurposed keeping in line with the prevalent ideas of sanitary urban planning. Accordingly, several prominent lakes such as the Miller's tank series of central Bangalore were drained as part of large scale epidemic prevention programs, further, and irrevocably transforming the waterscape. In a sense, therefore, the urban commons was replaced by a centralized vision of what infrastructure provision was meant to look like.

Colonial Ideas of Modernity and Technological Advancement

In addition to these new notions of health and hygiene, colonization of the city also brought with it its own ideas of modernity and the role of technology in enabling those ideas. If the notions of health and hygiene served to bring about a separation between native and European populations, colonial beliefs of the superiority of western technology and modernity served to further reinforce that divide. The colonial idea of modernity was built upon the promise of large infrastructural projects and the power of the engineer as a vehicle for delivering that promise. Accordingly, the construction of large dams, the creation of large interconnected systems designed to provide water into the city and transport sewage away from it, and the enabling of connectivity across large swathes of land—through roads, railways, electricity, and telephones.

Such interventions, while aimed at making the city more economically productive and resilient to disease, were based upon western understandings of the cityscape, and transplanted into colonies without consideration of the specific contexts within which they were being implemented. They also furthered the divide between the native and European populations in terms of differences in lifestyles and technologies they used. Native technologies were seen as inferior to those brought into the colonies by the west and as such this served to perpetuate the notion that these technologies needed to be replaced by superior modern ones. Accordingly, the role of engineers and large scale interventions in resource governance and management superseded the more decentralized infrastructure that was characteristic of precolonial tank management. This change in perception of the urban as a space supporting lives and livelihoods through localized resource systems into one driven by global economic concerns and supported by large scale infrastructural interventions further served to increase the disconnect between urban residents and the resources that once supported them.

Changes in Meanings Ascribed to the Utility of Resources

Changes effected from the top also brought with it associated changes within people who interacted directly with the waterscape. The interplay between increasing demands placed on land and water resources, associated rise of real estate and property values, changing notions of health, hygiene, sanitation, technology, and modernity resulted in shifting attitudes of resource users and dependents towards the waterscape of Bangalore. Water contained within the tanks began to be associated less with the sustenance of lives and livelihoods and more with their value as aesthetic or recreational adornments enhancing the beauty of the city. Over time, these ideals became more powerful, influencing decisions made over resource management and governance. At the same time, it resulted in the marginalization of those communities for whom the water body represented something other than these ideas of aesthetic or recreational utility. Our research on lost tanks of Bangalore (the Sampangi, today repurposed into the Sri Kanteerava Indoor and Outdoor Stadium, the Dharmambudhi—today the city's central bus station, and the Millers tanks—today an agglomeration of various residential neighborhoods and public infrastructure) shows that their decline was caused due to the interplay between changing urban imaginaries of resource utility, progressive marginalization of the communities of grazers, fishers, and farmers most dependent upon them and their resultant alienation from the resource, rendering the water body vulnerable to threats such as pollution, encroachment, and reclamation. The repurposing of these former water bodies reflects the dominant ideals that governed colonial urban planning—those of aesthetics and recreation (stadium), public infrastructure (Millers tanks in central Bangalore), and the desire for large interconnected hubs of transport (bus station).

Co-evolution of Novel Ecosystems in Colonial Bangalore

These changes had multiple consequences for the ecosystems of Bangalore, and the social-ecological connections they embodied. The connectivity between the lakes was lost, cutting off the flows of water characteristic to the city in its precolonial form. Livelihoods dependent on these water bodies such as agriculture, pottery, and fishing became increasingly marginalized and often relegated to the peripheral regions of the city. Livelihood commons associated with the water bodies such as grazing lands and village forests were destroyed, giving way to public infrastructure, educational institutions, and residential complexes that were constructed in their place.

In the colonial city, now distinctly urban in form and character, a divide began to emerge between spaces of human habitation and nature. Urban wildlife of the city became seen as a threat to human habitation, and the conquest of wildlife was seen as an achievement. Rewards were offered for the culling of wildlife, commensurate with the potential human hazard involved. Bears, tigers, cheetahs, snakes, scorpions, and elephants were systematically hunted to rid human habitation off "vermin." Organized hunts were set up often to the exasperation of villagers who objected to the thundering of horses across their fields and the worrying of livestock by the hunting dogs participating in these hunts.

Focus also shifted to improving the aesthetics and recreational utility of the urban form. Thus the creation of large gardens landscaped in the European manner with fountains and walkways, the incorporation of menageries in some of them (in which wildlife could be experienced), and the opening of these spaces at specific times of the day for recreation. Native plants and trees began to be replaced by imported species of vegetables, fruits and ornamental trees—with substantial investment into research to enable their cultivation on in India.

The novel ecosystem engineered by the precolonial inhabitants of Bangalore thus coevolved with the changing aspirations of the city. A change that was reflected through a flowing waterscape worshipped as sacred, now transformed into perennial sewage fed semi-stagnant and eutrophic water bodies, considered a health hazard. Through the relegation of urban wildlife to areas separate from human habitation, and the introduction and sustained propagation of those forms of biodiversity deemed to enhance the human experience of the urban. It was also a change that manifested through homogenizing societies as being aspirational of the dominant urban vision—and one that marginalized and slowly excluded livelihood-dependent communities or groups of people for whom the social-ecological system represented utilitarian benefits.

Engineering Urban Futures: Independent India, Technocracies, and Their Influence

The Independent State and Its Vision

Independent India continued to build on its colonially inherited infrastructure and retained focus on large scale technologies and infrastructural projects for the provision of water and other utilities. At the same time, there was a new emphasis on first expanding the public sector (from the 1950s into the 1990s) and later neoliberalizing the economy (from the 1990s onwards). Both of these events served to expand the boundaries of the city, while at the same time accelerating the repurposing of water bodies, associated channels, and other commons into further built structures. Accordingly, several additional lakes of the city were transformed into residential communities, malls, sports stadiums and public infrastructure. Surviving lakes further continued to act as a sink for the massive volumes of sewage discharged by the city as it grew and expanded beyond its colonial boundaries. Further, lifestyles dependent upon resource provisioning from water bodies (such as fishing) began to be regulated by centralized institutions, which oversaw the introduction of commercially viable exotic fish species into the ecosystem.

Ecological manifestations of system in response to the large scale changes wrought by these developments occurred gradually over time. One of the most noticeable effects of these changes was that of seasonal flash flooding in areas formerly occupied by water bodies or their channels, especially during the monsoons. Given that several of these areas are also occupied by the most vulnerable and marginalized of the city's population, these events have posed further challenges in terms of equity and justice within the social ecological system. There has been a decline in migratory water birds as a consequence of the loss of the city's lakes, wetlands and green cover. The depletion of ground water (owing to the loss of recharge function provided by lakes and a massive increase in borewells), and changes in rainfall, increasing prevalence of urban heat islands and other changes local microclimatic conditions have emerged as a consequence of ecosystem transformation.

Challenges posed by these changing social ecological system conditions have evoked multiple responses in recent years with calls and attempts to restore or rejuvenate the lost waterscape of the city. One of the earliest attempts to draw attention to the scale of the issue came in the form of a government report in 1987, which drew attention to individual lakes and their status. This was followed by documentations of bird diversity by naturalist groups who sought to spotlight the loss of lakes. Sporadic, but mostly unsuccessful attempts towards rejuvenating water bodies began in the 1990s, and by the early 2000s, there was a short-lived attempt to use Public Private Partnerships for restoring water bodies. Focus within these mechanisms however retained colonial notions of increasing the aesthetic, recreational, and real estate value of the water bodies. Little thought was devoted to the social-ecological system—thus these attempts converted the natural slope of lakes into “fishbowls,” lit up lakes at night with artificial light, replaced native vegetation with exotic ornamentals, and provided playgrounds, fountains and boating facilities for the urban recreationalist. Conversely, livestock owners, farmers, or commercial washer folk were denied access to these water bodies. Commercializing the water bodies meant the uninterrupted requirement of water within individual lakes that were mostly devoid of connectivity with others in the network—this necessitated tapping into deep groundwater aquifers to pump up water into the lake during summer or other periods of drought.

Community Collectives and the Promise of Coproduction

Beginning in the early 2000s, an increasing engagement with both the social and ecological components of the system led to the rise of citizen action, networking with state to rejuvenate their urban water commons. Two of the best known examples are those of the Kaikondrahalli lake in southwest Bangalore and Jakkur lake in the northern part of the city. In both of these cases, local resident groups have worked with the Government to rejuvenate these lakes while keeping ecological and social contexts in mind. Accordingly, while aesthetic and recreational benefits have been promoted through landscaping and the creation of jogging tracks, these are also used by livestock grazers and fishers. Local varieties of plants and trees have been encouraged, while fountains and night lights have been minimized as disruptive to biodiversity. Some open wells have been restored. These activities have been planned in conjunction with local vulnerable populations such as livestock grazers in ways that they can benefit from the arrangement. For example, in Jakkur lake, gardens include local medicinal plants that can be harvested by peri-urban village communities. Such efforts are not without their own challenges including those of networking effectively across diverse user groups and with local

bureaucracies, and systemic challenges such as dealing with large scale sewage inflow into the water bodies, and preventing encroachments by powerful land mafia.

Though localized, these efforts have succeeded in improving local social ecological system dynamics. For example, around both lakes, a number of nesting water birds can be spotted, including cormorants, pelicans, painted storks and other migratory water birds that had disappeared for some years but that have slowly started to return. Water quality within some of these lakes have been shown to have improved, also positively affecting the quality and catch of fish harvested from them. Socially, a sense of community cohesiveness (though still challenged by social inequities and power imbalances) has been brought about through these collective efforts lending hope for equitable and just urban futures within the city. These efforts have also proven inspirational to emergent collective action around other water bodies of the city, while at the same time, diversifying and scaling up into other sectors such as finding solutions to the city's traffic woes.

Conclusion: Quenching Urban Thirsts Within a Changing Waterscape

The story of Bangalore's shifting waterscape is one that is characterized by dramatic social and ecological transformations over time. It is a story of changes in the values of nature, the ideas of what constitutes the urban space, and the role that urban nature plays within the predominant vision of the city at a given point in time. For example, the creation of the originally engineered systems of interconnected water bodies was a reflection of the need for dependable sources of water in conditions of semi aridity, in order to sustain lives and agrarian or associated livelihoods. Its subsequent transformation, however, was dictated by changing visions of urbanity (for example colonial ideas of modernity and sanitation intertwined with the idea of an urban water body as being more aesthetic and recreational in utility). Adaptive management by communities in response to context specific challenges and associated positive and negative feedback loops have also played a major role in the production of this waterscape.

The city of Bangalore, is thus highly representative of an anthrome—a novel ecosystem—but one that has been so for several millennia. Changes within the anthrome are visible over large periods of time and reflect the co-evolution of nature with human society and processes of urbanization. These transformations have been a very integral part of the city's evolution over time, so much so, that the initial roots of the city are mostly forgotten by the vast majority of urban dwellers in Bangalore. Indeed, many residents of Bangalore remain unaware of the fact that the water bodies they now call "lakes" were manmade or that they were instrumental in the creation of Bangalore's identity as a Garden City.

While the idea of an anthrome is relatively new, the case of Bangalore as illustrated here is reflective of the fact the creation of an anthrome itself is not a new phenomenon. Bangalore is not unique either in being an anthrome of such long standing—these large scale human mediated transformations are an important character of urban spaces in many south Asian landscapes that have had long histories of human settlement. Indian cities such as Chennai or Mumbai, as well as other cities of the global south such as the Peruvian city of Lima or the Indonesian city of Jakarta have all recorded large scale human mediated landscape transformations in the form of water and irrigation works (some of which remain in use even today).

However, in today's age of the Anthropocene, the scale and intensity of human influence has increased greatly, leading to more pervasive and dramatic landscape changes. We now deal with newer challenges brought on by changing lifestyles (for example an increased dependence on plastics leading to the widely publicized problem of marine and coastal plastic accumulations). This in turns creates a need to find new ways of managing social and ecological systems in ways that pay attention to the fragility, finitude, and fairness of both the social and ecological components of the system.

For example, in the case of Bangalore, one of the ways traditionally used to manage sewage pollution in lakes was what was referred to as "natural sewage treatment." It consisted of making use of natural vegetation and wetlands in and around the water body to filter incoming loads of sewage, while at the same time diluting its concentration through the seasonal monsoons of the region. This coupled with annual desilting programs was sufficient to maintain these lakes. Unfortunately, this approach proved incapable of dealing with the 21st century city, which receives large volumes of sewage and diverse sources of polluted water. Systemic changes in response to these have already been developed and are being widely implemented—sewage treated through Sewage Treatment Plants is now being directed into the water bodies. In other words, seasonal monsoons have a reduced role in filling up the water bodies—instead they are continually being replenished by treated sewage. Many lakes have thus transformed from seasonal, rain filled, to perennial and sewage filled, impacting their ecological processes and biodiversity. However, policy and institutional arrangements have not kept pace with these developments, a situation that can have long lasting impacts on the region.

On the social front too, while today there are still livelihood groups such as farmers and fishermen dependent upon the water bodies, their numbers are constantly declining with newer generations opting towards more "urban" livelihoods and occupations that are not dependent on ecosystems. The importance of lakes as sacred spaces, important to sustaining resource dependent occupations is also waning. It is unlikely that the system can revert into its older form that was aimed at sustaining an earlier form of socio-cultural engagement with ecology—what is more likely is that urban water commons will continue to gain more traction as aesthetic and recreational utilities. Indeed, the history of the urban water commons of Bangalore, that we have illustrated earlier, shows that this change is already well underway.

Consideration of these aspects is very important in the larger contexts of the Indian city (as also other cities of the global south) that on the one hand are struggling to meet their burgeoning demands of development, and on the other dealing with issues of sustainability. These issues are further compounded by the increasingly visible effects of climate change—an increase in extreme

events (floods, earthquakes, and heatwaves among others), leading to an exponential increase in the number of climate migrants finding their way into more urban spaces. What is needed therefore in this new era, is consideration of whether these changes can be made equitable and just. Can the new age urban planning regime foster a sense of inclusivity within the planning process itself—one that pays attention to the many ways in which urban commons—the anthromes—are ecologically and socially relevant in the production of the urban space?

Abstract

Cities are dominated by impervious surfaces and by vegetation planted and managed by people. These urban features affect arthropod abundance, distribution, and phenology and can influence how arthropods interact with each other and with their host plants. In this article we first explore the mechanisms by which the features of urban anthromes affect arthropod herbivores and their natural enemies. We then consider how cities shape, at regional and global scales, arthropod invasion dynamics, biotic homogenization, and overall species distributions and how these patterns are affected by background climate. Lastly, we look to the future and consider how insect ecology on urban trees may continue to change as the world becomes warmer and more urbanized. We highlight how changes in abiotic conditions and biotic interactions may influence arthropods and their response to urbanization. Cities are as complex as the humans that plan them and the biota that occupy them. Regarding cities as dynamic systems will help us design landscapes and management strategies that protect urban trees and the organisms that depend on them.

Introduction

Humans can shape ecological processes in cities by altering the physical environment and by directly and indirectly affecting plants and animals (Frankie and Ehler, 1978; Raupp et al., 2010; Dale and Frank, 2018). For example, when planners choose the location and size of green spaces, their decisions affect local temperature patterns and habitat connectivity for mobile organisms (Burkman and Gardiner, 2014). When residents determine how many and which plants to install in their yards, these choices influence how attractive the yard is to certain animals (Burghardt et al., 2009). Arthropods are widespread in cities, respond strongly to the features of human-dominated environments, and have the potential to both contribute to and reduce the benefits provided by wildlife in urban areas (Raupp et al., 2010). However, people often make decisions about urban landscapes without consideration for how arthropods might be affected.

In cities, herbivores (e.g., aphids, caterpillars) and arthropods in higher trophic levels (e.g., spiders, parasitoid wasps) may rely directly and indirectly on managed plants for oviposition sites, shelter, food resources, or refuge from predators (Frankie and Ehler, 1978; Raupp et al., 2010). Trees, in particular, often provide key habitat for arthropods in urban areas (Raupp et al., 2010). Many of the arthropods living on urban trees are considered beneficial from the human perspective, such as pollinators and arthropods that support charismatic animals (e.g., songbirds) at higher trophic levels (Narango et al., 2017). However, urban trees can also support herbivore pests, which can damage trees and reduce tree benefits or even directly cause harm to humans (Dale and Frank, 2018). For

*Both authors contributed equally to this work.

example, oak processionary caterpillars (*Thaumetopoea processionea*), which release hair-like structures that cause allergic reactions in people and pets, live on planted urban trees in London, England (Tomlinson et al., 2013). Regardless of whether people explicitly consider arthropods—both beneficial and harmful—when making management decisions, human choices in urban landscapes influence arthropods.

In this article we will discuss how urban environments affect arthropods and their interactions with other organisms. We will focus specifically on temperate “dense settlement” anthromes (Ellis et al., 2010) that have high human population densities and are dominated by urban land cover (Fig. 1). In the first section we will discuss how human choices about land cover, especially managed vegetation and impervious surfaces like roads and buildings, can directly and indirectly affect arthropods on a local scale. We focus primarily on herbivores, which are essential for urban food webs but are also frequent pests on managed plants. We also focus on the natural enemies, such as predatory beetles and parasitoid wasps, that help to control herbivore populations. Herbivore and natural enemy responses to urban features at a small, local scale can also drive larger patterns. Therefore, in the second section we will consider how cities shape, at regional and global scales, arthropod species distributions and invasion dynamics and furthermore how these patterns are affected by background climate. In our last section, we look to the future and consider how insect ecology on urban trees may continue to change as the world becomes warmer and more urbanized.

Arthropod Responses to Urban Features

Vegetation and Arthropods in the City

Vegetation diversity and complexity

Human choices about trees in cities, especially about which species to plant and where to plant them, affect herbivores and their natural enemies. Both on individual city blocks and in the city as a whole, the diversity and homogeneity of tree species are the product of many individual human choices. Overreliance on a single tree species can facilitate the rapid spread of some pests, such as the emerald ash borer (*Agrilus planipennis*), which has caused significant tree losses as it has invaded North American cities that have high densities of green ash (*Fraxinus pennsylvanica*) (Raupp et al., 2006). To safeguard against disease and pest risk, practitioners and researchers have recommended increasing urban tree diversity, and some cities have even created rules for the proportion of trees of a given taxon that can be planted along city streets (Paap et al., 2017; Raupp et al., 2006; Santamour Jr., 1990). In addition to being at lower risk of catastrophic tree loss due to invasive herbivores, urban landscapes with high plant diversity and habitat complexity may also have fewer chronic pests (Fig. 2). For example, pine needle scale insects (*Chionaspis pinifoliae*) were more abundant on pines in simple “impoverished” landscapes, such as roadsides and parking lots, compared to pines in more complex wooded habitats (Tooker and Hanks, 2000). Natural enemies may contribute to these patterns, as habitats with greater complexity provide predatory and parasitic arthropods with alternative prey and carbohydrate resources, cooler microclimates, and refugia from predators (Gardiner et al., 2009; Landis et al., 2000). However, not all natural enemies respond equally to changes in vegetation or habitat complexity in urban areas, and additional mechanistic studies could inform the design and management of urban areas to promote natural enemies and pest control services on city trees (Burkman and Gardiner, 2014).

Tree species selection

Tree species selection in urban areas depends on many factors. A resident may attempt to simultaneously support animal biodiversity, avoid pests, and provide shade to reduce energy costs. Recommendations based on one of these criteria, for example to plant native plants to support arthropod biodiversity (Burghardt and Tallamy, 2013), may conflict with recommendations for the other criteria. In addition, it is not clear whether patterns observed on trees in suburban and rural areas apply in densely urbanized areas where features like habitat connectivity, plant stress, and temperature play important roles in structuring arthropod communities.

People’s choices about which tree species to plant in cities may be guided by aesthetic or maintenance priorities, ecosystem services (e.g., stormwater reduction), or the desire to support biodiversity, including herbivorous arthropods (e.g., caterpillars) that support higher trophic levels (e.g., birds). To date, the discussion about selecting plant species that support arthropod biodiversity in ornamental landscapes has focused on a distinction between “native” and “non-native” plant species. Native trees are generally described as those that evolved in the geographic area of interest, while non-native species are those that evolved elsewhere and were introduced to the new area, such as through the ornamental plant trade. Due to a coevolutionary history, native herbivores may have an easier time locating native plants and avoiding or tolerating these native plants’ defenses (e.g., defensive chemicals) compared to plants with which they share no coevolutionary history (Ehrlich and Raven, 1964). As a result, native plants may host a greater diversity and abundance of some insect herbivores, which may support fauna at higher trophic levels (Burghardt et al., 2009; Burghardt and Tallamy, 2013; Frank et al., 2019). This is frequently considered a positive attribute of native plants. For example, in Maryland, United States, residential yards planted with native plants supported more caterpillars and birds than yards planted with non-native plants (Burghardt et al., 2009). However, native herbivores may also reach injurious levels on native plants in cities, requiring management action and/or reducing tree health (Dale and Frank, 2014; Meineke et al., 2013; Raupp et al., 2010).

Because arthropods in higher trophic levels do not feed directly on plants, they may be less sensitive to plant origin than herbivores (Procheş et al., 2008). In a study conducted in Raleigh, North Carolina, United States, scale insect abundance was higher on native maple (*Acer*) and oak (*Quercus*) trees than on non-native congeners, but predator and parasitoid abundance, diversity, and community composition were similar between the native and non-native trees (Frank et al., 2019). In contrast, Greenstone et al. (2017) found more spiders consuming brown marmorated stink bug (*Halyomorpha halys*) egg masses in native ornamental

landscapes than in non-native ornamental landscapes. Overall, the effects of plant origin on arthropods in higher trophic levels are understudied in cities, and more research is needed to determine how human decisions about native and non-native plant species affect natural enemies and their capacity to control pest populations in urban areas.

Temperature and Arthropods in the City

Arthropods are ectotherms and are sensitive to changes in temperature. Cities are often several degrees warmer than surrounding rural areas, a phenomenon known as the urban heat island effect (Oke, 1973) (Fig. 1). Even within a city, an arthropod can encounter both hot and cold spots (Fig. 1). Some pest species reach higher densities, have faster development rates, and/or achieve higher fecundity in areas with elevated temperatures (Dale and Frank, 2017; Zvereva and Kozlov, 2006). In metropolitan Seoul,

Fig. 2 Variation in local landscape around urban trees. Trees are planted in many different urban conditions and habitats. The picture to the left depicts a tree surrounded by dense amounts of vegetation and higher habitat complexity, which may provide habitat for natural enemies that can control tree pests. The two pictures on the right depict trees planted in areas with high amounts of impervious cover and little vegetation. These trees may be more likely to have hotter tree canopies and fewer natural enemies.

South Korea, cicada population densities increase with temperature (Nguyen et al., 2018). In Raleigh, NC, United States, oak lecanium scales (*Parthenolecanium quercifex*) are more abundant in hot parts of the city due to acclimatization or adaptation to high temperatures as well as reduced control by natural enemies caused by a phenological mismatch (Meineke et al., 2013, 2014). Understanding which herbivores have higher fitness in warmer areas and how plant damage by herbivores may change with urbanization will ultimately help landscape managers better prioritize pest targets in urban areas that pose the most risk to trees.

Impervious Surface and Arthropods in the City

Impervious surfaces, such as buildings and roads, often replace vegetation in urban environments (McKinney, 2008) (Fig. 1). The addition of impervious surfaces, which absorb and reradiate heat, coupled with the loss of cooling vegetation, result in higher temperatures in cities compared to outlying areas (Oke, 1973). Some insect species respond positively to environments dominated by impervious surface. Impervious surface cover is the best predictor of both egg density of horse chestnut scale (*Pulvinaria regalis*) in Oxford, United Kingdom (Speight et al., 1998), and presence of Asian citrus psyllid (*Diaphorina citri*) in California, United States (Thomas et al., 2017). Other arthropod species, especially those with sensitive habitat requirements, may have lower fitness or survival in areas with high impervious surface cover. For example, native Lepidoptera species richness declined with the replacement of habitat with impervious surfaces in San Francisco, CA, United States (Hafernik and Reinhard, 1995).

Impervious surface cover may affect arthropods through plant-driven effects like changes in plant water and nutrient availability. Some arthropod species thrive in areas where trees are water stressed, potentially due to their ability to capitalize on changes in plant defense and nutrient allocation that sometimes occur when plants are water stressed (Dale and Frank, 2017; Speight et al., 1998). In Raleigh, NC, United States, gloomy scale (*Melanaspis tenebricosa*), which feeds on parenchyma cells, reaches higher densities on red maples (*Acer rubrum*) surrounded by impervious surface due to additive effects of warmer temperatures and higher plant water stress (Dale and Frank, 2017). In contrast, aphids, which feed on plant phloem, have lower abundance on water stressed plants, a phenomenon attributed to reduced turgor pressure in plant tissues that makes phloem harder to access (Huberty and Denno, 2004).

Within a city, the abundance of vegetation in an area is typically inversely related to impervious surface cover (Blair and Launer, 1997; McKinney, 2008) (Figs. 1 and 2), which can result in less habitat for natural enemies and fewer natural enemies that control pests. Hanks and Denno (1993) attributed greater scale abundance on mulberry trees in urban landscaped planting beds to reduced habitat complexity and fewer generalist predators when compared to mulberry trees in urban forest areas. Impervious surface can also indirectly affect top down control of tree pests by fragmenting habitat and reducing the ability of some natural enemies to travel among patches and control plant pests (Burkman and Gardiner, 2014; Niemelä and Kotze, 2009). For example, ground beetles (Carabidae), many species of which are predaceous and are sensitive to ground cover changes, are less abundant and diverse in urban areas where impervious cover is high (Niemelä and Kotze, 2009).

Overall, changes in herbivore communities associated with changes in impervious cover can mean that herbivore damage on urban plants is affected as well. For example, chewing damage was lower on seven species of broadleaf trees in urban areas with

more impervious cover when compared to natural areas (Nuckols and Connor, 1995), potentially a result of fewer chewing herbivores in urban areas. Alternatively piercing-sucking herbivores are often abundant in urban areas (Hanks and Denno, 1993; Just et al., 2018; Meineke et al., 2013; Raupp et al., 2010), which may mean more piercing-sucking damage on plants in areas with high impervious cover.

Regional and Global Patterns: Scaling Up From the City Block

Individual arthropods respond to small scale changes in their local environment. Within a single city block of a dense settlement anthrome, insects are navigating different microclimates, encountering different food plants and prey resources, and interacting with plants that may be stressed by harsh urban conditions. The specific responses of arthropods to these local conditions shape distributions of arthropods within a single city. Some patterns of arthropod responses to urban features are replicated across cities, but others are unique due to the environmental or social context in which a city is embedded.

Effects of Background Climate on Arthropods in Cities

Certain features of cities, such as impervious surfaces and the urban heat island effect, are common to many urban areas around the world (McKinney, 2006). However, cities are embedded in landscapes with a wide range of climates, which may affect arthropod responses to urbanization. Arthropods in tropical areas tend to tolerate a narrower range of thermal conditions and live closer to their thermal optima than arthropods at high latitudes (Addo-Bediako et al., 2000). As a result, urban warming may push arthropods in tropical areas beyond their thermal optima, reducing their fitness, but benefit arthropods living at high, colder latitudes (Diamond et al., 2015; Youngsteadt et al., 2017). In mid-latitude cities, responses are expected to be highly variable (Youngsteadt et al., 2017). In a study of four temperate North American cities spanning 6.6° of latitude, Youngsteadt et al. (2017) found that at the highest studied latitude, insects on urban trees tended to benefit from warm urban temperatures. In mid-latitude cities, there was not an overall positive or negative response because of large variation, with populations of some taxa increasing and others decreasing with urban warming (Youngsteadt et al., 2017).

In some cases, factors associated with urbanization may be more important than background climate for predicting arthropod responses. In Europe, herbivory was lower on woody plants in cities than in adjacent rural areas, a pattern which was independent of latitude but was stronger for cities with a larger human population (Kozlov et al., 2017). The abundance of gloomy scale (*Melanaspis tenebricosa*), a key pest of red maple (*Acer rubrum*) in urban areas in the southeast United States, increased with urbanization in eight cities independent of latitude, likely due to combined effects of temperature and water stress on trees surrounded by impervious surface (Just et al., 2019; Dale and Frank, 2017). In their study of insect communities on urban trees in four cities, Youngsteadt et al. (2017) found that, in contrast to expectations based on latitude, insects declined with urban warming where urbanization was most intense (Queens, New York, United States), possibly because of factors like habitat fragmentation and isolation that were more important than temperature. These studies and others demonstrate that cities may disrupt theoretical ecological patterns related to climate and arthropods in non-urban settings, which complicates predictions about how to manage plants and arthropods in cities throughout the world.

Effects of Vegetation Distribution on Arthropods in Cities

On a global scale, climate is among the most important drivers of vegetation structure and diversity, but human activity can disrupt natural patterns in plant distribution (Ellis et al., 2012). For example, though the native ecosystem in Los Angeles, CA, United States, is drought-deciduous shrubland, non-native trees with high water requirements (e.g., sweetgum, *Liquidambar styraciflua*) are grown in the city with help from landscape irrigation systems (Pataki et al., 2013). In naturally forested regions, urban plant communities differ from forest communities due to the routine planting of non-native tree species in cities and filtering out of species that cannot survive in urban conditions (McPherson et al., 1997; Raupp et al., 2006).

A single ornamental plant species may be grown in cities both on and off its continent of origin, resulting in overlapping tree species compositions in geographically distant cities (Kendal et al., 2012). Many non-native insects are introduced in cities as a result of the ornamental plant trade, the trade of other goods, or through intentional introduction by humans (Paap et al., 2017). Combined, the introductions of plant and arthropod species contribute to the homogenization of arthropod communities in cities that are geographically distant (McKinney, 2006). Homogenization of arthropod fauna in cities can involve both specialist and generalist insects. When specialist insects are transported with their host plants to regions with favorable abiotic and biotic conditions, they can establish populations outside their native range. Crape myrtle (*Lagerstroemia indica*) is planted on several continents besides its native Asia, and its specialist aphid, the crape myrtle aphid (*Tinocallis kahawaluokalani*), is also found in many of these locations which are geographically far apart (e.g., North America and Africa) (Mizell et al., 2006). Generalist arthropods are typically more successful in urban areas than specialists, in part because urban features or scarce host/prey resources may filter out species with sensitive habitat requirements (Burkman and Gardiner, 2014). Since features like impervious surface, pollutants, and habitat fragmentation are common to many cities around the world, a generalist insect that thrives in one city may thrive in others if introduced.

Arthropod Invasion Dynamics in Cities

When an arthropod is introduced and establishes in an urban area, it can potentially invade non-urban areas. Because of this, cities are sometimes called “beachheads” or “bridgeheads” for invasion (Cadotte et al., 2017; Paap et al., 2017). Cities are good beachheads because rates of introduction of non-native species are high and because they provide environments where some invasive species are likely to thrive and establish populations (Cadotte et al., 2017). For organisms that are limited by cold, the urban heat island effect or human infrastructure may contribute to higher winter survival. For example, at the northern end of its range in the US, the mimosa webworm (*Homadaula anisocentra*) has higher survival when it overwinters on heated buildings, allowing it to survive in the city at latitudes that would otherwise be too cold (Hart et al., 1986).

In addition to tolerating the abiotic conditions, an organism invading a new area must also interact with other organisms. For herbivores, establishment is only possible where suitable host plants are available. Because cities have different plant compositions than natural areas, they may offer host plants for invasive arthropods that are not available or are limited outside the city. The crape myrtle bark scale (*Eriococcus lagerstroemiae*), detected in the United States in 2004, attacks crape myrtle (*Lagerstroemia indica*) trees, which occur predominantly as ornamental trees in their introduced North American range (Wang et al., 2016). An introduced organism may experience less pressure from natural enemies, especially specialist natural enemies, in its introduced range (Bauer et al., 2005) and encounter lower competition in the city than it would encounter outside the city (Cadotte et al., 2017). These biotic factors increase the likelihood that a species can establish once it is introduced. Once established, there is potential for the species to invade new areas. Global insect invasions continue without saturation (Seebens et al., 2017), suggesting that the challenges of managing insect pests on urban trees will only continue to grow.

Looking Forward: Managing Arthropods on Urban Trees

Plant-arthropod interactions in cities are dynamic and are affected by evolutionary processes, environmental change, and human decisions. The drivers of plant-arthropod interactions we have discussed thus far, such as responses to urban and background temperatures and human choices about native and non-native plants, are all happening at the same time. In this final section, we will highlight some key considerations and main ideas about managing urban trees and arthropods while major global changes like urbanization and climate change continue to interact.

Plant Effects

Plants are already responding to anthropogenic climate change and will continue to be affected by climatic changes in future decades (Lobell and Gourdji, 2012). The combination of elevated temperatures and atmospheric carbon dioxide is expected to alter plant nitrogen content and defense compounds in ways that affect herbivores’ performance on their host plants (Zvereva and Kozlov, 2006). Ultimately, both herbivores feeding directly on plants and arthropods in higher trophic levels are likely to respond to changes in the abiotic and biotic environments.

Changes in plant water stress may be a particularly important consideration for landscape practitioners managing pests on urban trees in the future, as many urban trees are already growing in hot and dry conditions. Additive effects of elevated temperature and plant water stress caused by impervious surfaces in urban environments and worsened by climate change may mean higher densities of some pest species (Dale and Frank, 2017). Wood borer attacks typically increase with plant water stress (Huberty and Denno, 2004; Koricheva et al., 1998) and some species, such as southern pine beetle (*Dendroctonus frontalis*) and mountain pine beetle (*D. ponderosae*) are also already responding to elevated temperatures caused by climate change (Cudmore et al., 2010; Lesk et al., 2017). Thus wood borers may be important priority pest targets for landscape managers, particularly in light of recent outbreaks of mountain pine bark beetle (*D. ponderosae*), emerald ash borer (*Agrilus planipennis*), and others outside of their native ranges (Cudmore et al., 2010; Raupp et al., 2006). However, as highlighted in this article, not all pests respond similarly to plant water stress (Huberty and Denno, 2004; Koricheva et al., 1998). Ultimately, better understanding of which pests may be most affected by water stress and warming temperatures will help managers identify pests of greatest concern on urban trees.

Natural Enemy Control

Not all arthropods are expected to respond to climate change and urbanization in the same way. Fragmentation of habitat for some natural enemies created by the addition of impervious surfaces may mean fewer natural enemies to control pests on city plants in a more urban future (Burkman and Gardiner, 2014). Phenological mismatches are another possible mechanism for reduced natural enemy control of pests in cities in the future. In Raleigh, NC, United States, oak lecanium scales (*Parthenolecanium quercifex*) at hot urban sites produced eggs earlier than those at cold urban sites, but parasitoid wasps did not similarly advance their phenology at the warmer sites (Meineke et al., 2014). Though the parasitoid wasps attacked scales at similar rates at hot and cold sites, the scale insects at hot sites had a head start on egg production that allowed them to escape control by the parasitoid wasps. Phenological mismatches like these between pests and their natural enemies could have negative implications for pest control and ultimately may be a priority area of concern for managers of urban trees, particularly for those pests that respond positively to urban warming.

Cities as Sentinels of Climate Change

Climate change experiments are expensive and logistically difficult. Present day cities, which are often 2–3 °C warmer than surrounding areas, can serve as living laboratories to explore questions about how organisms may respond to future climate changes (Lahr et al., 2018). Using a comparison of scale insects on present-day urban and rural forest trees, as well as historical herbarium specimens collected from forests, Youngsteadt et al. (2015) found that herbivores' responses to urbanization provide useful clues about their responses to background climate warming. In particular, scale insect abundance was higher on trees in warmer areas of the present-day city, on historical specimens collected during warm periods, and in present-day (warmer) rural forests compared to the same forests historically. From a management perspective, a correlation between arthropod responses to urban and global warming introduces the possibility of using cities to make informed predictions about which pests may be of growing concern in the future. However, cities will not work as sentinels in all cases. Some arthropods may respond more strongly to urban features like pollutants, frequent disturbance, or impervious surfaces than to temperature. Long-lived organisms, like trees, which are difficult to grow and study for warming experiments, organisms with life history traits which are highly sensitive to warming, and organisms with low dispersal capability to move beyond city limits may be the best candidates for studies attempting to link responses to urban and global warming (Lahr et al., 2018). Continued studies of arthropod communities across urbanization gradients will make it possible to distinguish shared patterns in responses of certain taxa or feeding guilds to urban and global warming and further inform management.

Interacting Effects of Urbanization and Climate Change on Arthropods

Organisms' responses to urbanization may interact with responses to climate change, for example if climate change affects individuals within and outside cities differently. Interactions between urbanization and background temperature are apparent in present-day studies of the effects of urbanization along latitudinal gradients. For example, organisms often advance their phenology in response to warmer urban or warmer background temperatures, but in a study of butterflies at 83 sites in Ohio, United States, ranging from undeveloped to urban, Diamond et al. (2014) found that butterfly phenology was delayed for seven of twenty species when urban warming was combined with latitudinal (i.e., background) warming. Exploitative species, including those that can feed on many different host plants or have multiple generations per year, had smaller delays in phenology. These results suggest that organisms may show idiosyncratic responses to climate change in urban areas, where urban heat may push some organisms beyond their thermal optima but move other organisms closer to their optima. In some cases, arthropods that are currently pests in cities may be unable to tolerate the additional warming caused by climate change and management activity could be reduced. However, if species benefit from the combination of urban and background climate warming, pest problems in cities are likely to increase in the future, particularly for exploitative species that are already causing problems in urban areas, such as invasive or generalist insect pests.

As the climate continues to change, cities may affect arthropods' geographic ranges. Many non-native arthropod species are initially detected in urban areas, where trade activity introduces new species and warm urban conditions may facilitate their establishment (Paap et al., 2017). For arthropod species that are expanding their ranges due to climate change, movement of individuals to cities may effectively increase their expansion rate. The northern boundary of the range of the pine processionary moth (*Thaumetopoea pityocampa*), native to northern Africa and southern Europe, has been expanding northward for decades due to increases in minimum winter temperatures (Battisti et al., 2005). In the 2000s, the species was moved by people (via ornamental plants) beyond the northern edge of its range to the Paris, France, area, where warmer urban temperatures buffered cold winter temperatures in this location (Robinet et al., 2012). At the southern end of the range, survival is not limited by cold, and thus the warmer temperatures in cities may not benefit the organism and could even be detrimental. As this example highlights, cities may play an important role in shaping organisms' distributions as the climate continues to change.

Managing Arthropods in the City and Beyond

The amount of Earth's surface classified as dense settlements is expected to increase in coming decades. Because humans control the planning of our cities, there will be opportunities to manipulate landscape plantings, set aside land for greenspace, and reduce impervious surfaces in ways that may reduce pests on urban trees, support tree health, and promote biodiversity. Cities can provide places where landscape managers can experiment and design solutions to mitigate the potential negative effects of global change and to make cities healthier for people and other organisms. The lessons learned from these management experiments and decisions can be used to guide management beyond city limits too.

Ecological relationships, including those on urban trees, are often non-linear, and arthropods' responses to a warmer climate and warmer cities will likely be complex. Cities can act as an ecological filter for certain species and types of traits, such as effective dispersal, and drive eco-evolutionary feedbacks (Alberti, 2015; Niemelä and Kotze, 2009). As a result, management strategies developed for present-day arthropods may become less effective as species living in urban areas continue to evolve. Despite these challenges, planners, managers, and designers have many tools they can currently use to minimize pest risk on urban trees. By considering a few key trends and studies, such as those highlighted in this article, planners and designers may be able to identify priority pest targets and explore management strategies that can protect the health of urban trees in a warming climate and a changing world. For example, selecting trees that are more drought-resistant and better adapted to urban conditions may help

reduce the risk of pest outbreaks and promote the long-term health of trees. Implementing regular watering regimens for urban trees could also be another strategy to help prevent water stress and reduce pest densities and damage. Furthermore, tree planting is often suggested as both a mitigation and adaptation strategy for climate change because trees sequester and store carbon and also have a cooling effect on their surrounding environment (Meineke et al., 2016; Nowak and Dwyer, 2007). Because pest problems are often reduced in parts of a city with high tree canopy cover, this strategy may help to reduce or avoid emerging pest problems as the global climate continues to warm. Planting a diversity of trees in urban forests and a diversity of plants around trees could also be a strategy to promote habitat for natural enemies that control tree pests and reduce overall risk of pest outbreaks.

Strategies that reduce pests on trees in cities may also reduce pests in surrounding areas. As described in this article, many non-native pests are introduced to novel environments for the first time through cities, so reducing the spread of pests on city trees may prevent infestation of forests and other habitats in surrounding areas. Cooling cities through strategic tree plantings may also reduce the use of cities as overwintering sites for some pests that may spread to other areas. Lastly, lessons learned about strategies to control pests in one city may be informative for other cities with a similar climate, as biotic homogenization of flora has made cities more similar across the globe.

Arthropods will continue to play an important role in cities as climate change, globalization, and urbanization continue. The choices we make today about managing plants and arthropods in cities will inform the solutions of tomorrow and promote the health of people and ecosystems in urban areas and beyond.

Abstract

Global farming and food systems drive at least 39% of land use. Cropland, an intensive and extensive land use, drives almost 15% of land use. However, the distribution of this land-use type and historical land cover change is heterogeneous. Clear clusters of cropland anthromes exist globally (e.g., the Midwestern United States), in grassland and Mediterranean biomes, and in Indomalaya and Oceania biogeographic realms. However, the spatial alignment of these clusters varies historically. Agriculture, and in particular cropland, has clear impacts on ecosystem structure and function. However, biodiversity conservation is a priority in many regions with an active debate in the literature as to the best pathways forward. In part, this reflects the unique characteristics of cropland anthromes including frequent tree cover and multifunctional land use.

Global Patterns in Cropland

Land dedicated to farming and food systems is estimated to cover at least 39% of the world's ice-free surface (Foley et al., 2005). While rangeland covers a greater percent, cropland is more intensive as a consequence of regular cultivation and frequent increasing applications of chemical inputs. In the global classification system of anthromes, farming systems are embedded in three anthrome types; rangeland, village, and cropland (Ellis et al., 2010). Our focus here, cropland anthromes, hold just over half of the world's arable cropland (Ellis and Ramankutty, 2008). Cropland anthromes are a heterogeneous landscape with patches of trees and pasture embedded in the arable farmland matrix. As such, this anthrome should be viewed as a multifunctional landscape with the potential for combining food, fiber, and fuel production with other landscape goals including biodiversity conservation, recreation, and a diversity of other valued states and functions (Allen et al., 2018).

Though there were initially five cropland anthrome sub-classifications (Ellis and Ramankutty, 2008), the subsequent analysis processes applied in Anthromes V2 (Ellis et al., 2010) reduced the number of cropland anthromes types or sub-classifications to four; placing populated irrigated and populated rainfed croplands together. The four additional types are residential irrigated cropland, residential rainfed croplands, populated croplands, and remote croplands. The four types of cropland anthrome vary most clearly as a function of population density and source of water. Irrigated and rainfed residential croplands have a population density (persons km⁻²) of 74 and 68, respectively. The population density in populated croplands density is 12 and is less than 2 people per km⁻² remote in remote croplands.

In 2000, cropland anthromes were 15% of anthromes globally (Fig. 1). Residential irrigated croplands and remote croplands were classified as one and 2% of global anthromes respectively, populated cropland, 5%, and residential rainfed cropland 7%.

Qualitatively, cropland anthromes have the greatest concentration in temperate regions including central North America and western Eurasia with clear clusters in sub-Saharan Africa, southern Australia, and South America, and Indonesia (Fig. 2). Residential Rainfed Cropland has the greatest concentration in Western Eurasia, Populated Croplands are most frequent in the east-central United States. Remote cropland anthrome is clear in the Great Plains of north-central North America and in Australia. Residential Irrigated anthrome is scattered within California (NA) and the Mississippi Alluvial Valley in North America, Mexico, the Middle East, France, southern Patagonia.

Cropland anthromes are most frequent in temperate regions broadly (> 80%) and specifically within grassland (51%), Mediterranean (45%), temperate broadleaf (40%), and tropical forest (30%) biomes (Fig. 3). Strikingly, over 50% of temperate grassland biome would be classified as cropland anthrome. This pattern of change closely parallels the top four biomes ranked by habitat converted in Hoekstra et al. (2005), though the tropical forest subtypes differ.

If we sort percent change by biogeographic region (Fig. 4) we see that Oceania and Indomalaya have the greatest percent of the region as cropland anthromes (> 20%), though all regions are over 11%. Within biogeographic regions, types of cropland anthrome vary (Fig. 5). For example, in Australasia, which has the lowest percent change overall, is dominated by remote croplands, Indo Malay and Afrotropic by residential croplands, and the Nearctic the most even.

Fig. 1 Change in percent global coverage of each cropland anthrome between 1700 and 2000.

Fig. 2 Global extent of cropland anthromes. Data from Ellis EC, Klein Goldewijk K, Siebert S, Lightman D, and Ramankutty N (2010) Anthropogenic transformation of the biomes, 1700 to 2000. *Global Ecology and Biogeography* 19: 589–606.

Unique Traits of Cropland Anthromes

In addition to extensive arable land, cropland anthromes have a number of other unique traits. For example, 15% of people live in these four anthromes. The human population of cropland anthromes is lower than that of the Villages and Dense Settlements but is still a significant portion of the global population. However, most of the people benefiting from arable croplands do not live in croplands, suggesting that telecoupling, or a connection across longer spatial distances, is key to consider. Trees are also common in these landscapes. Indeed, cropland anthromes contain about a quarter of global tree cover (Ellis and Ramankutty, 2008). As a consequence of trees, frequent pastures, and intensive plant growth of selective crops (e.g., corn, soybean, wheat, cotton, Fig. 7), cropland anthromes have a greater share of net primary productivity (NPP) than the entire wild forests biome (Ellis and Ramankutty, 2008). However, it is interesting to note, that a significant portion of this NPP is appropriated for human consumption, a process discussed in the article in this volume on Human Appropriation of Net Primary Productivity (HANPP).

An Expanding Anthrome

The spatial extent of cropland has increased over the last 300 years (Fig. 1) but at a slower rate in the last 60 years (Fig. 6, FAOstat from Food and Agriculture Organization of the United Nations, 2019). Globally, cropland anthromes increased from 2.6% to 14.7% of global cover between 1700 and 2000 datasets (Fig. 1). This growth is not evenly distributed, with only Europe remaining relatively constant (further discussion below). Residential Rainfed cropland was the most extensive throughout (~2%–7%). Residential irrigated croplands remain under 1% of global anthrome cover across each anthrome century. But undoubtedly their impact is broader given that the water they use is drawn from beyond the extent of the croplands. Tilman et al. (2002) show how the footprint of irrigation increased globally between 1960 and 2000. The anthrome data (Figs. 2 and 5) provides one data point on how intensification via irrigation has spread heterogeneously but in key locations, as discussed below. Importantly, during this time use of chemical fertilizers and pesticides also increased globally (Tilman et al., 2002) magnifying the ecological impact of agricultural expansion on biodiversity (discussed below). Cereals have long been the most abundant crop (Fig. 7, FAOstat from Food and Agriculture Organization of the United Nations, 2019) with oil crops increasing most rapidly in the last 60 years. Importantly, the continued increase in yields has not slowed the expansion of cropland (Rudel et al., 2009).

Regional Heterogeneity in Spatial and Temporal Patterns of Croplands

There is clear regional variation in both spatial and temporal patterns of cropland anthromes. For example, cropland anthromes were already dominant in western Europe and the Middle East by 1700 but expanded in eastern Europe between 1800 and 2000 (Fig. 8). The footprint of irrigated cropland is most obvious in 2000, particularly in the Middle East and western Europe.

Fig. 6 Global yield and area harvested (1960–2017). Data from FAOstat.

Fig. 7 Global area harvested of 10 key global crops. Data from FAOstat.

In contrast, in North America, cropland anthromes were largely absent in 1700, and even 1800. Indeed, the greatest change in the extent of cropland occurred between 1800 and 1900 (Fig. 9). The northern Great Plains have most recently increased in cropland, likely shifting from rangeland between 1900 and 2000. Since 1900, intensification via increased irrigation has occurred in the south-central and western parts of the region. Like western Europe, clusters of cropland anthromes were already evident in southeast Asia in 1700 (Fig. 10A). Interestingly, the extent of cropland declined in southeast Asia. However, the extent of village anthromes is much more extensive in the 2000 dataset (Fig. 10B).

Threats to Cropland

Despite the global extent and historical expansion of cropland, recent spatial data analyses suggest that key croplands may be lost to other land-use types. For example, d'Amour et al. (2017) suggest that we could lose 1.8–2.4% of global cropland by 2030. These are not marginally productive agricultural lands either, as their data suggest, this could result in a 3.4–4.2% loss of production. Given the expected increases in global population and consumption, loss of cropland is an essential conservation question. Indeed, van Vliet et al. (2017) project continued loss, particularly as a consequence of the expansion of urban land use and land cover disproportionately on land that is ideally suited to farming and food systems. This suggests a more complex narrative around croplands and conservation where patterns of interaction between agriculture and other institutions or systems are regional and context-specific.

Biodiversity Conservation Within Cropland Anthromes

Given the extent of cropland globally, much research has been focused on how to best protect biodiversity in cropland anthromes given the demand for food, fiber, and fuel (e.g., Krebs et al., 1999; Batáry et al., 2010; Meehan et al., 2010; Fahrig et al., 2011; Quinn et al., 2017). Agriculture is frequently faulted for habitat loss and species decline. The current economic efficiency of replacing a diversity of perennial plant communities with a limited number of annual monocrops, coupled with government subsidies, has resulted in agriculture being the dominant matrix of many landscapes worldwide. Unlike ranching and forestry, conservation efforts within the agricultural matrix are discounted because of the low expectations of farmland as a source of ecological stability and biodiversity. However, because agriculture is a dominant land-use, conservation efforts need to consider how this matrix can be managed to enhance associated wild biodiversity.

In a conservation context, it is helpful to have a sense of patterns of richness across anthromes (Martin et al., 2014). At a global extent, the median richness per pixel of plant (Ellis et al., 2012) bird, amphibian, and mammal communities is greatest in residential rainfed cropland (Fig. 11; data from Jenkins et al., 2013 and Pimm et al., 2014). Relatively there are the fewest number of threatened birds and amphibians in remote croplands and the fewest threatened mammals in residential irrigated croplands (Fig. 11). A broader review of richness by anthrome type is available in Cook and Quinn, this volume.

Much of the debate on biodiversity conservation in cropland anthromes has focused on the spectrum of conservation actions between land sparing and land sharing (or wildlife-friendly farming) (Green et al., 2005; Fischer et al., 2008). More recently this discussion has moved from considering the extremes of these options to reflecting how they can be incorporated together appropriately at a given scale and in a given location (Quinn et al., 2014; Fischer et al., 2014).

It is interesting to compare the focus of conservation in cropland anthromes between different areas. The contrast between systems is best demonstrated between Europe and North America. From a research perspective, Europe has gone so far as to define a group of wild species that have a specific relationship with agriculture. In particular, the United Kingdom, as part of its nationwide health assessment, has included a group of birds classified as “farmland birds”. These species may or may not have been present in the same relative abundances 100 or 1000 years ago, but have adapted to the dominant agricultural land use in the region, though threats to these species exist as agriculture intensifies. Across Europe, birds and farming have a long history. These species likely did not thrive in the historical wooded land cover of the region but adapted to thrive under the low-intensity agriculture. More recently, as a result of farmland intensification, the status of these populations has declined, leading to calls to protect farmland species. In contrast, in North America there remains a focus on species classified by biome or ecosystem type; for example grassland birds. And conservation research and practice focus more on cropland expansion versus intensification. However, we have seen many species decline precipitously over the last 50 years, corresponding to the intensification of cropland (Quinn et al., 2017). Future research should consider how these differences drive conservation and farming policy. The anthromes data provides one way to give spatial context to this observation. In comparison to the extensive history of complex interaction and co-evolution between agriculture and biodiversity in Europe seen across the historical anthrome data the relationship between the two in North America, particularly in the Great Plains is recent and impactful. Thus birds and farming in North America have a much shorter relationship, with little time for species to adapt in response to land cover change. There is also value in examining tropical agroecosystems, which have been home to many efforts to balance production and conservation. A combined focus is arguably needed to address the response of biodiversity to agriculture.

Organic farm management has been shown to aid species conservation efforts in croplands. When compared to similar non-organic farm systems, organic farms frequently demonstrate greater richness and abundance of multiple taxa (Hole et al., 2005). As a result, organic farm management is frequently classified as wildlife-friendly farming rather than as land sparing (Green

et al., 2005; Fischer et al., 2008). However, because organic regulations vary by country and often stipulate only what practices cannot be used, the adoption of species-friendly practices and associated land use and land cover patterns can vary greatly between and within farms (Gabriel et al., 2010). Organic agriculture is among the most rapidly growing sectors of agriculture. In 2006, farmland was certified organic in over 135 countries, totaling over 30 million ha and 0.65% of worldwide agricultural area (Willer et al., 2009). Almost a quarter (24%) of organic land is found in Europe, 16% in Latin America, and 7% in the United States. Within each region, the share of total agricultural land that is certified organic is 1.62% in Europe, 0.68% in Latin America and 0.57% in North America (Willer et al., 2009). Despite its small footprint, organic farming has frequently been evaluated for its contribution to biodiversity conservation.

Conclusion

In summary, cropland anthromes are a dynamic, multifunctional, and linked global and regional systems. The extent of this anthrome has increased globally in the last 400 years as has the intensification of cropping systems. In addition to their local footprint, cropland anthromes are connected to populations globally via our current farming and food system. Cropland anthromes however are more than just farmland. They are important population hubs, contain significant tree cover, and are central to current and future conservation efforts.

Abstract

Humans and rangelands have a complex and intertwined history. Rangelands provide many goods and services to humans, and humans have altered rangelands through their activities. Land potential describes the capacity for production of ecosystem services utilizing the inherent properties, resistance, and resilience of a location. The alteration of land potential by humans has led to changes in how these landscapes function and the ecosystem services they provide. Understanding current and future human needs along with the history of a landscape allows for land potential to act as a filter for management decisions. By combining inherent properties of a site with resistance and resilience along with knowledge about past management activities, land potential can help managers identify not only limitations but also opportunities for investment of resources that are both ecologically and economically positive on the landscape.

Rangelands and human beings have a complex relationship where rangelands provide many goods and services necessary for human sustenance, and humans undoubtedly influence the production of these goods and services. Food, fiber, water, and energy are fundamental human necessities produced by these systems. Being the most extensive human influenced biome, the rangeland anthrome covers nearly one third of the Earth's ice-free surface but only accounts for 5% of the world's population (Ellis and Ramankutty, 2008). Among the many variable definitions of rangeland, most incorporate a land cover type (e.g., "land on which the indigenous vegetation is predominantly grasses, grass-like plants, forbs, or shrubs and is managed as a natural ecosystem" (SRM Glossary of Terms, 1998)) combined with a land use that typically emphasizes grazing or pastoralism (Lund, 2007). Rangelands support 50% of global livestock production (Millennium Ecosystem Assessment (MEA), 2005) although they account for less than 15% of terrestrial net primary production (Ellis and Ramankutty, 2008). There is no doubt that provisioning services (i.e., meat and fiber production) are important contributions of rangelands, however there are numerous additional ecosystem services (supporting, regulating, and cultural) that are receiving increased attention (Briske et al., 2017a,b).

Anthropogenic pressure on rangelands has increased with human population and the associated demands for food and shelter (Millennium Ecosystem Assessment (MEA), 2005). Following European settlement and expansion of railroad infrastructure, United States rangelands were primarily used for livestock production (Holechek, 1981) and the exploitation of natural resources led to significant changes in many rangeland systems (Sayre et al., 2012). Anthropogenic impacts often altered the potential of rangelands to produce the goods and services required for our continued existence, and the level of anthropogenic pressure determined the degree to which rangeland potential was impacted. This historic overutilization of rangeland resources left a legacy of degradation, and current land management must account for these constraints.

Describing these heterogeneous and expansive landscapes can be difficult, especially when considering anthropogenic impacts and uses. The concept of land potential, however, provides a practical approach to contextualize opportunities and limitations of a given piece of land. Land potential is composed of three distinct elements: potential production of one or more ecosystem services, resistance of the land to degradation, and resilience following disturbance (Herrick et al., 2013). This concept utilizes the inherent properties of a site along with anthropogenic influences to determine the capacity of that site to produce goods and services (Fig. 1). This framework effectively represents pertinent rangeland processes and functions, because it factors in the history of human interaction with this complex landscape.

In this article, we provide a framework for addressing rangelands and the anthropogenic pressures they are facing through the lens of land potential. First, we discuss the inherent properties that govern land potential, followed by the concepts of resistance and resilience within the land potential definition, and then the ecosystem services that humans rely on rangelands to provide. After establishing the land potential concept and framework, we discuss how humankind has altered and continues to alter land potential

Fig. 1 Elements of and anthropogenic influences on land potential.

across a variety of rangelands using examples mostly from the United States. We conclude with a discussion of land potential assessment and how this framework could be used to make sustainable rangeland management decisions concerning ecosystem service provisioning.

Fundamentals of Land Potential

The capacity of a rangeland to sustain ecosystem services, resist degradation, and recover following disturbance can be captured in the concept of land potential (Herrick et al., 2017). Within the land potential framework, climate, soils, and landscape position determine the potential plant and soil biological communities and ecosystem processes. Together, these properties and processes determine an inherent range of ecosystem services produced by the landscape. Any alteration to these components leads to a corresponding change in ecosystem services. Land potential, much like soil, is a malleable characteristic that is determined first by inherent properties that can be both static (e.g., soil physical properties, parent material, etc.) and dynamic (e.g., plant and soil biological communities, etc.), which can change naturally over millennia or through anthropogenic influence at much shorter time scales.

Inherent and Dynamic Properties

Inherent, or relatively static, properties of a system, like climate, soils, resident plant community, etc., and the functions they facilitate define land potential within an area. Climate is fundamental to our understanding of how landscapes develop. Temperature and precipitation regimes favor certain plant and soil biological communities in specific areas, and soils develop at different rates under different climatic patterns. Rangelands developed where combinations of temperature and precipitation regimes favor grass and shrub species on a wide range of soils. Climate, both historical and present, influences biological community dynamics and soil formation, and given that climate impacts the inherent properties of a location, climate along with disturbance regimes will also drive land potential when viewed at broader spatial scales.

Disturbances are events that place pressure on ecological systems leading to partial alteration of natural ecosystem function (Nimmo et al., 2015), and are usually categorized by the type of pressure that is placed on an ecosystem (Lake, 2000). Pulse disturbances, like wildfire and flood, are discrete events that impact an area on a limited time scale and allow time for natural recovery following the event. Ramp disturbances, like drought, begin by putting slight pressure on the system, which is then exacerbated as the disturbance continues. Lastly, press disturbances are often anthropogenic, like urbanization and land development, and place long-term pressure put on an ecosystem that are never alleviated and can, therefore, force complete alteration of ecosystem function. Historic disturbance regimes, like wildfire, flood, and drought (Lake, 2000; Nimmo et al., 2015) are typically characterized by the frequency, intensity, and duration of naturally-occurring disturbances and determine how an ecosystem would normally respond to any such event.

Climate, geology, and geomorphology are broad-scale properties of an area that heavily influence how the disturbance regime affects the development of other finer-scale characteristics, like soil physical properties and resident plant community. Soil physical properties include relatively dynamic properties such as available water holding capacity (AWC), infiltration capacity, bulk density, and physical crusts, and shape land potential through impacts to rangeland processes (Herrick and Brown, 2016). They also include relatively static soil properties such as texture (i.e., soil particle size distribution) and mineralogy (as influenced by parent material), which affect some ecological functions (e.g., erosion control and nutrient cycling) both directly, and through their effects on the relatively dynamic properties. Soil texture correlates strongly with AWC and infiltration, and is a major influence on soil stability, all key indicators of land potential. Mineralogy affects soil chemical properties, like pH, electrical conductivity, and sodium adsorption ratio (SAR), which impacts soil stability as well. Soil aggregate stability is a metric for soil surface resistance to degradation, and often, a change in this is linked to a related change in soil texture or soil chemistry and can be indicative of soil loss or deposition, which directly impacts land potential on the landscape. Rangeland soils have highly variable physical and chemical properties, can be especially complex when considering the wide range of climate, precipitation, and disturbance regimes (Briske et al., 2017a,b).

High variability in rangeland soils is compounded by the almost equally variable landforms. Landscape position (i.e., where the site is on the landscape) and soil erosion are strongly related to one another as well as the inherent soil physical properties. For example, soils that are found in depositional, lowland areas are often vastly different from upland soils occurring within the same landscape, resulting in very different inherent potential of the system (Herrick et al., 2017). Landscape position is also generally related to soil depth and nutrient availability, and other factors such as degree of incline and slope contour influence how water flows over the soil surface along with erosion potential. Landscape position and soil stability can also have significant influence on the vegetation types we can expect to see and even affect soil biological communities.

Plant community composition is a dynamic property that determines the short-term potential of land to sustain ecosystem services (e.g., erosion and climate control, pollination, food, fiber, etc.) and influences historic disturbance regimes of that area. Thus, changes in plant community composition or function can reflect alteration of land potential due to modification of rangeland processes. In rangeland systems, vegetation communities are often identified by a combination of resident plant community (i.e., what species are expected to be present and in what assemblages), as well as plant functional groups represented (e.g., blue grama grassland, sagebrush shrubland). Describing plant communities based on functional traits is useful for rapid biological and ecological characterizations of rangelands, but may not fully describe the land potential due to omission of many important soil properties (McGill et al., 2006; Walker, 1992).

Although plant communities are comparatively easy to describe, soil biological communities are often much more difficult to characterize. Soil bacterial and fungal community diversity, richness, activity, and relative abundance are also very dynamic, and can have a significant impact on short-term land potential as they have large impacts on soil nutrient cycling and availability, as well as soil aggregate stability. Changes in these communities following disturbance can therefore indicate alterations in ecosystem process and function (Seaton et al., 2019; Landgenheder et al., 2010). Biological soil crusts are a component of the soil biological community that play a key role in landscape function and land potential. Biological soil crust communities include cyanobacteria, fungi, eukaryotic algae, lichens, and moss and are restricted to the first few centimeters of the soil surface. These communities are characteristic of arid and semi-arid rangelands and are often associated with interspace regions devoid of vegetation. Measurements of relative abundance and diversity of soil biological communities can indicate biological stressors within the soil as some community members are more tolerant of harsh conditions (Seaton et al., 2019; An et al., 2013). Soil biological crust communities can also influence characteristics related to soil erosion such as runoff extent and velocity. Knowledge of soil biological communities adds to the overall understanding of land potential, and can help inform estimates of soil resistance to degradation or ability to recover following disturbance.

Resistance and Resilience

Resistance and resilience are two additional components of ecosystems that define land potential. Both concepts were born from the ecological resilience theory developed in the 1970s at population and community scales (Holling, 1973) and have since evolved in usage at the landscape scale (Carpenter et al., 2001; Nimmo et al., 2015; Briske et al., 2017a,b). The two concepts of resistance and resilience are specific to each ecosystem and are determined by the inherent abiotic and biotic characteristics of that system along with the historic disturbance regime. Ecological resilience theory describes how a system acts in the face of disturbances, natural and anthropogenic (Holling, 1973). Resistance is the capacity of a natural system to withstand disturbance and retain its function, whereas resilience is the capability of an ecological system to return to previous stability or to reorganize itself with renewed functionality (Seybold et al., 1999). Abiotic and biotic components of ecosystems interact within natural disturbance regimes to determine how that system reacts and responds to the disturbances present during its development. Because resistance and resilience are process-based characteristics of a landscape, they are applicable at almost any scale of observation (both temporal and spatial), and coarser-scale usage is needed to understand the impacts to land potential. Although natural events have shaped resistance and resilience of all ecosystems, many systems have lost some of their natural capacity to withstand external influence due to anthropogenic alteration of historic disturbance regimes and subsequent impacts to the inherent characteristics of a landscape.

Utilizing resistance and resilience with the land potential framework can provide some guidance when trying to predict how ecosystems will function under altered disturbance regimes (Lake, 2013). The scale and scope of human interactions with rangeland systems requires consideration of natural ecosystem response when faced with anthropogenic disturbance. By acknowledging and understanding how a system naturally responds, these natural responses can provide guidance for land management decisions in the face of continued human pressures.

Resistance and resilience are also key to the production of ecosystem services on rangelands throughout the world. When ecosystem function is maintained or improved, rangelands provide many important ecosystem services. Resistance and resilience help determine the capacity of an ecosystem to withstand disturbance while maintaining functionality, which directly contributes to the sustained production of many key ecosystem services.

Land Potential and Ecosystem Services

The supply of rangeland ecosystem services, or the benefits humans receive from rangeland ecosystems (Millennium Ecosystem Assessment (MEA), 2005), are directly dependent on the various aspects of land potential, which is driven by inherent biophysical properties as well as anthropogenic influences on ecosystem properties (Fig. 1) (Brown and MacLeod, 2011). Rangelands are often characterized as having highly heterogeneous biophysical properties. When coupled with diverse land use histories, the resulting land potential and associated ecosystem services on a landscape are frequently diverse.

The Millennium Ecosystem Assessment (MEA) placed ecosystem services into four broad categories representing provisioning, regulating, supporting, and cultural services (Table 1) (Millennium Ecosystem Assessment (MEA), 2005). Given the anthropocentric nature of ecosystem services, the values placed on them vary across user communities (e.g., producer, conservation, recreation, cultural), socioeconomic status, and gender, to name a few (Martín-López et al., 2012). Demand also drives emphasis placed on certain ecosystem services. For example, in U.S. rangelands emphasis has generally been placed on provisioning services or those that could directly be harvested by humans (e.g., food, fiber, energy, or water). Over the last 150 years the primary provisioning resources produced on these rangelands have evolved in direct response to demand shifting from predominantly sheep to cattle production and the expansion of fossil fuel based energy resources to clean energy resources such as wind and solar (Yahdjian et al., 2015).

Table 1 Potential anthropogenic influences on production of select ecosystem services.

<i>Ecosystem services</i>		<i>Range management examples of anthropogenic influences on sustainable production of ecosystem services</i>	
<i>Class</i>	<i>Example</i>	<i>Positive</i>	<i>Negative</i>
<i>Supporting</i>			
Primary production		Land management decisions (e.g., timing, frequency, intensity of disturbances) and restoration of degraded plant communities to maximize primary production.	Land management decisions that reduce primary productivity.
<i>Provisioning</i>			
Food		Technological advances and improved techniques for livestock production.	Overutilization of grazing resources, competing land uses (housing developments, energy, etc.)
Water		Ground and surface water allocations/use based on known or projected availability.	Unsustainable use of ground and surface water for production purposes.
Energy		Allocation of rangeland for energy production.	Policy restrictions limiting the use of rangelands for oil, gas, wind, or solar production.
<i>Regulating</i>			
Air quality		Restoration activities that promote soil stabilization, proper timing of prescribed fire, proper fuels management to reduce wildfires probability outside of historical regimes.	Increased particulate matter due to degraded/destabilized plant and soil biological communities eolian erosion of soil and natural/prescribed fire outside of the historical range of variability.
Erosion control		Restoration activities that promote soil stabilization (e.g., revegetation, grazing strategies, placement of roads and fences).	Increased loss of soil due to degraded/destabilized plant communities.
<i>Cultural</i>			
Recreation		Policies to promote multiple use of public lands.	Loss or degradation of land available for recreation purposes (e.g., hiking, biking, camping, bird watching).
Spiritual values		Protection for areas used for spiritual purposes.	Loss of culturally important plants, soil, rocks, and minerals restricting their availability for spiritual purposes.

Examples of Anthropogenic Influence on Land Potential

Effects of forage overutilization arise from stocking grazing animals at a rate in excess of the carrying capacity of land for an extended amount of time (Derner et al., 2017). Human-induced changes to the land from this process may result in either positive or negative changes in land potential. Positive human impacts include land improvement through implementation of sustainable land use practices (e.g., conservative stocking, drought monitoring, timing of grazing, periods of rest) with the goal of increasing resistance and resilience to future degradation. Negative human impacts resulting from overutilization include the unsustainable removal of biomass, soil compaction, increased erosion potential, and even increased albedo, which could lead to reduced evapotranspiration and rainfall (Millennium Ecosystem Assessment (MEA), 2005; Sala et al., 2017). The overutilization of grazing resources following settlement of the American west has weakened resident above- and belowground biological communities in many areas, which has had drastic impacts on land potential. Overgrazing in conjunction with drought only intensifies the negative impacts on ground-cover, diminishing the possibility for full recovery (Treydte et al., 2017). Globally, this “human-induced” driver of change is often credited with being the reason for rangeland abandonment and the relocation of pastoralists and rural populations (Millennium Ecosystem Assessment (MEA), 2005). The emphasis on livestock production has decreased the value of the landscape to provide wildlife habitat, control erosion, and effectively cycle nutrients, all resulting from unsustainable grazing practices (Sayre et al., 2012).

The effects of human activities on land potential have been documented in many other parts of the world including east Africa. In Kenya, rangelands are primarily used for traditional livestock raising by nomadic pastoralists (Fratkin, 2001). Additionally, African rangelands provide habitat that supports many native wildlife species (Georgiadis et al., 2007). Communal use of the landscape has led to large areas of degraded rangeland due to the overutilization of grazing resources, similar to the American west. Accelerated erosion and soil loss have led to reductions in numerous ecosystem services, including providing wildlife habitat, and the demand for resources provided by the land has increased rapidly over the past few decades (Millennium Ecosystem Assessment (MEA), 2005). To combat this reduction in land potential, many international programs (IRP, 2019) have focused on restoration and rehabilitation of soil resources throughout the region (see Kimiti et al., 2017). By improving resistance and resilience through restoration and rehabilitation of the landscape, land potential can be increased to support increased ecosystem services.

The prairie ecosystems of the North American Great Plains were historically among the most productive rangelands in the world. Given their high land potential associated with productive soils, favorable climate, and gentle terrain, it is no surprise that much of its extent has been altered via cultivation following European settlement (Sampson and Knopf, 1994). Historically, indigenous peoples predominantly used the region for hunting and gathering resources due to the large populations of wildlife and diversity of native flora throughout the area, and utilized areas along waterways for small-scale crop production. The conversion of these prairie systems to intensive crop production by European settlers reshaped key ecosystem services provided by this landscape as well. Due to intensive management and introduction of significant external inputs such as fertilizer, one specific ecosystem service has been augmented at the expense of many others. Current management in this region is for crop production, and provisioning services (food and ethanol production, in this case) far exceed what the landscape naturally provided. Although provisioning services have increased, the capability of the system to provide regulating and cultural services has been significantly impaired. External inputs of fertilizer impact nutrient cycling and water quality, and traditional cultivation increases soil loss by inhibiting erosion control. The implications of widespread conversion to croplands to wildlife are mixed, favoring habitat generalists like robins and pheasants at the expense of native grassland specialists such as prairie chickens and horned larks (Knopf, 1994; Askins et al., 2007). Additionally, this habitat loss impacts many species of butterfly and other important pollinators (Moranz et al., 2012). From the relics of this system that still exist, we are still learning how significantly the conversion has altered the services provided. Although many services have been changed, the benefits to human society via increased production and revenue overall outweigh most of the negative impacts, and new cultivation techniques are developing that help to restore some of these services.

Assessing Land Potential

With an understanding of how historic land potential has been altered by anthropogenic influences, the question remains: How do we gauge land potential? Many assessments rely on historic accounts and records to describe the potential natural vegetation of an area (Udvardy, 1975; Olson et al., 2001). These classifications are typically based on climatic characteristics along with plant physiology and soil properties to estimate the potential productivity of the area (Prentice et al., 1992). These groupings allow managers to understand what plant communities would historically have been present on sites and the related ecosystem services provided. Others attempt to describe the dynamics of a site with an emphasis on state and transition models that include process-based thresholds that dictate disturbance response, which influences resistance and resilience (Bestelmeyer et al., 2003; Stringham et al., 2003; Briske et al., 2005). Spatial and temporal scale is also a key consideration when determining how to assess land potential and new tools are emerging to facilitate this.

Advances in quality and accessibility of remote sensing data along with increases in computing power have allowed for the integration of machine learning and artificial intelligence systems to estimate land potential through determination of potential natural vegetation along with human influence at global scales (Ellis et al., 2010; Hengl et al., 2018). At more local scales, LandPKS, a mobile phone application, was developed for site-specific determination of land potential (Fig. 2) (Herrick et al., 2013, 2017). This tool predicts the available water holding capacity and infiltration rate for an area based on inherent site characteristics

Fig. 2 Using LandPKS to evaluate land potential.

such as slope, rock content of the soil, and soil texture by depth, while allowing the user to adjust these numbers based on soil organic matter, which is a relatively dynamic property that can be affected by management. Available water holding capacity serves as an ideal measurement of production potential because it integrates many other site characteristics in its calculation (e.g., soil texture, rock fragments, organic matter). Along with a measurement of land potential, LandPKS also offers users a way to monitor trends on the landscape through plant community measurements that facilitate flexible management strategies (Herrick et al., 2017).

Managing Within a Rangeland Potential Framework

When land potential has been adequately characterized, land managers can use this concept to evaluate their ability to achieve management goals on a given piece of land. Although understanding land potential alone will not guarantee a positive outcome, it can be used to develop a more complete understanding of the opportunities and limitations that exist for a given piece of land. Land potential can be used to prioritize restoration treatment (e.g., revegetation, herbicide) locations for favorable responses and avoid some locations where there would be a high probability for a negative response like soil erosion (UNEP, 2016). Making ill-informed management decisions can translate into economic loss, environmental degradation of biotic and abiotic resources, and depending on the land's resilience, lasting negative impacts to the ecosystem services that land supports.

Selection of treatment locations for brush control provides an example of how land potential could be used in management decisions. In this scenario, there are two locations within a management unit undergoing woody plant encroachment that are candidates for treatment. Using the land potential concept to evaluate both sites, managers determine that, although both sites are visually similar, inherent soil properties are quite different. One site has a shallow soil with a root-restricting layer of caliche at 20 cm depth, and the other is on a deeper soil without any restrictive layer. The available water capacity (as measured by LandPKS) on the former site is less than 2 cm and on the latter site is ~5 cm. With the filter of land potential, the latter site would be identified as the more appropriate location for brush control treatment due to a higher likelihood of positive response. By understanding the fundamentals of land potential within a management context, one can make effective and efficient decisions regarding implementation of management activities.

Land potential provides a meaningful filter for the evaluation of landscapes at all spatial and temporal scales. By combining inherent properties of a site with resistance and resilience along with past management activities, land potential can help managers identify not only limitations but also opportunities for investment that are both ecologically and economically positive on the landscape. Land potential can and should be used in concert with other tools available to land managers that describe the processes occurring on the landscape (e.g., Ecological Site Descriptions, State and Transition Models, etc.). Utilizing land potential in conjunction with other tools allows for the optimization of land management strategies to fulfill specific objectives and represents an underlying framework that can be used for decision-making across scales and locations.

Abstract

The proposed designation of the Anthropocene suggests a triple challenge of preventing biodiversity loss, mitigating and adapting to climate change, and sustainably providing resources for a growing human population. Anthromes often take the form of multifunctional mosaics of perennials and annuals (e.g., agroforestry systems). Biodiversity-based land management of working lands has been practiced since ancient times and their value has been recognized, updated and promoted across our global biomes over the past forty years. Analogous agroforestry systems are found in common biomes across the globe. Agroforestry incorporates an array of successful strategies, historic and modern, that have relevance for achievement of multiple Sustainable Development Goals (e.g., biodiversity, climate change, poverty alleviation). Four agroforestry biomes are described, both historic and modern, that will play an important role in helping to achieve global Sustainable Development Goals. These include: (1) Mediterranean anthrome (dehesa/savanna with livestock); (2) Highland/lowland/island tropical anthrome (homegardens and multi-strata systems); (3) Temperate zone anthrome (silvopasture, alley cropping—silvoarable); and (4) Arid/semi-arid tropical anthrome (improved fallows, farmer-managed natural regeneration, evergreen agriculture).

Introduction

More than three quarters of the terrestrial biosphere have been reshaped by humans into anthropogenic biomes (anthromes), embedding substantial areas of remnant and recovering novel ecosystems within the agricultural and settled landscapes that sustain human populations (Ellis and Ramankutty, 2008). Anthromes often take the form of multifunctional mosaics (e.g., agroforestry systems) within which substantial remnant and less intensively managed ecosystems are often left embedded, especially where terrain is heterogeneous (Ellis, 2013; Van Noordwijk et al., 2019b).

The proposed designation of the Anthropocene suggests a triple challenge of preventing biodiversity loss, mitigating and adapting to climate change, and sustainably providing resources for a growing human population. Proper management of “working lands” (i.e., farms, forests and rangelands) is needed in order to address this triple change. These working lands must be managed both to complement the biodiversity conservation goals of protected areas and to maintain the diverse communities of organisms, from microbes to mammals, that contribute to producing food, materials, clean water, and healthy soils; sequestering greenhouse gases; and buffering extreme weather events, functions that are essential for all life on Earth. Temperate and tropical agroforestry systems are directly connected with Sustainable Development Goals (SDGs), goals which are needed to be reached address the loss of biodiversity, climate change and regenerative farming (e.g., soil health) at both large and small scales (Van Noordwijk et al., 2018; Van Noordwijk et al., 2019b). The creation of SDGs has enabled multifunctional land uses, including agroforestry, to gain wider support. An integrated landscape approach, with increased functionality per unit of land, appears to be the best way of coherently targeting the SDGs (Van Noordwijk et al., 2018).

Agroforestry focuses on the role of trees on farms and in agricultural landscapes to meet the triple bottom line of economic, social and ecological needs in today's world. Across the globe, the science and practice of agroforestry can contribute to many of the SDG key challenges: (1) Hunger eradication based on agroforestry methods of soil fertility and land regeneration; (2) Market driven, locally focused tree cultivation systems that generate income and build assets to lift more rural poor from poverty; (3) Advance the health and nutrition of the rural poor through increased use of plant diversity; (4) Conservation of biodiversity through

Fig. 1 Ecoregions categorized within 14 biomes and eight biogeographic realms (Olson et al. 2001). Similar temperate and tropical agroforestry anthromes correspond to similarities across ecoregional biomes.

integrated conservation solutions using agroforestry technologies; (5) Protecting watersheds and water quality through agroforestry-based solutions; and (6) Assisting rural poor to better adapt to climate change through intentional cultivation of a diverse array of tree/shrub crops (Garrity, 2004; Nair et al., 2017).

An important dimension of biodiversity for agroforestry is the representation of trees in local knowledge and the degree of specificity of ethnobotanical knowledge, linked to culture, language and ethnicity. Across a wide range of settings and agroforestry anthromes, total tree diversity ranges from 10 to 1000 species. For example: (1) 100 indigenous species were located in tree diversity surveys in 16 villages in Burkina Faso, Mali, Niger and Senegal (Cámara-Leret et al., 2019); (2) A total of 127 species were identified with acknowledged local use value in homegardens plus coffee agroforestry systems in Southwestern Ethiopia (Jemal et al., 2018); (3) A total of 190 tree species were noted in coffee-based multi-strata agroforestry systems on the slopes of Mount Kenya (Carsan et al., 2013); (4) and hundreds of native tree species are currently found in agroforestry ecosystems in the Peruvian Amazon (Dawson et al., 2008), forming an important reservoir of biodiversity.

These multifunctional land management strategies, found throughout the world across temperate and tropical biomes (Fig. 1), represent a major opportunity to ensure sustainable production of food and fiber along with the ecological heritage of the planet (Ellis, 2013; Nair et al., 2017; Kremen and Merelender, 2018; Udawatta et al., 2019). Four major global agroforestry anthromes, rooted in history and currently under active use, will be covered including:

1. Mediterranean anthrome (dehesa/savanna with livestock).
2. Highland/lowland/island tropical anthrome (homegardens and multi-strata systems).
3. Temperate zone anthrome (silvopasture, alley cropping—silvoarable).
4. Arid/semi-arid tropical anthrome (Improved fallows, farmer-managed natural regeneration, evergreen agriculture).

Mediterranean Anthrome (Dehesa, Silvopasture)

The Mediterranean basin anthrome is dominated by silvopasture systems which include the Spanish *dehesa* “La Dehesa”, also known as “*Montado*” in Portuguese. The term “*dehesa*” comes from Spanish and refers to land in Southeast Spain set aside as free pastures for roving shepherds and herds belonging to the “*mesta*.” The *dehesa* is a human influenced agroecosystem in continuous use for centuries (Martín-Vicente and Fernández-Alés, 2006).

Climate is the primary identifying characteristic of the Mediterranean *dehesa* biome, defined by marked variation of seasons, a hot and dry summer (from 3-11 months), with a period of limited rain during the relatively cold season that extends from autumn

to spring. Rain is erratic and therefore its distribution throughout the year is as important as its total value. In addition to the Mediterranean basin, this type of climate also exists in California, along the Pacific coast of South America (Chile), in South Africa, and in Southeast Australia (Le Houérou, 1993).

The Mediterranean dehesa, a traditional agroforestry system, includes more than 3 million hectares of the Iberian Peninsula. Similar systems are found in northern Greece, Crete and Corsica (Eichhorn et al., 2006). Dehesas average 500 ha but there are systems that are as large as 5000 ha. The hot, dry summer climate of the Dehesa requires a relatively large area to support enough pasture for livestock, and rotational grazing is practiced as a key to management approach in order to be ecologically and economically viable (Moreno and Pulido, 2009).

The dehesa is a savanna-based silvopasture system, where livestock, disbursed trees and shrubs, pasture and crops all have important roles. Dispersed trees are combined with crops, pasture and shrubs as a result of the different management practices focused on agriculture, livestock, forestry and game. Dehesas are used for extensive livestock raising (sheep, cattle and pig) and cereal cultivation in long rotations. The trees have a direct value as fodder crop, providing acorns and leafy branches in autumn and winter, when the herbage production is low, and an indirect value as shelter for cold in winter and heat in summer. As a consequence, the trees are planted, managed and regularly pruned with the aim of maximizing acorn production (Martín-Vicente and Fernández-Alés, 2006).

Components of the System

The dehesa anthrome is not only characterized by diversity in species (fauna and flora), but also by structure and production. The system consists of an open tree layer (50 trees ha⁻¹) and an annual grass layer, whose composition and functioning largely depend upon the tree layer. The tree layer is typically composed primarily of evergreen species of *Quercus* (*Q. rotundifolia*, *Q. suber* L., *Q. faginea*), although other deciduous *Quercus* are also common (*Q. pyrenaica*, *Q. pubescens* Willd., *Q. canariensis* Willd.) (Martín-Vicente and Fernández-Alés, 2006).

Domestic livestock are the primary product of the dehesa and as such the tree and forage components of the system are based on the nutritional needs of the livestock. At its most basic form, the dehesa contains a two-strata structure, herbaceous and arboreal. The herbaceous forage layer typically consists of natural pasture, however crops and improved pasture are also used. The arboreal layer includes low density disbursed trees, typically ranging from 20 to 40 trees per hectare (10–50% canopy ground cover). Trees are maintained to provide diverse products to the system (fruits, fuel wood, cork, fodder) as well as for protection of the soil and herbaceous layers (Moreno and Pulido, 2009).

The Holm oak (*Quercus rotundifolia*) and cork oak (*Q. suber*) are the most frequently used tree species in the Iberian Peninsula. The holm oaks are found in the interior regions and the cork oaks are present in the more temperate and humid regions, with more Atlantic influence. Holm oak are excellent producers of sweet acorn, while the cork oak is valued for cork production. Other species present in the more humid dehesas include other oaks (*Q. faginea* and *Q. pyrenaica*). These tree species are valued for fodder since branches can be pruned for food in periods of pasture scarcity (Moreno and Pulido, 2009).

A highly diverse layer with a half dozen of shrub species is common in dehesas including *Cistus* sp., *Retama* sp., *Erica* sp., *Arbutus unedo*, and *Viburnum tinus*. The shrub layer includes species that have a high nutritional content for domestic livestock and for game species (Hajer et al., 2004).

Intentional establishment of trees within dehesas is a traditional practice. The predominance of *Quercus ilex* subsp. *ballota*, which produces a sweeter acorn than other oaks, is attributed to the active role of humans in the tree establishment within the dehesa (Martín-Vicente and Fernández-Alés, 2006).

Highland/Lowland/Island Tropical Anthrome (Homegardens and Multi-Strata Systems)

Tropical homegardens, found across the globe in fertile, moist tropical lowlands and highlands, are intimate, multi-strata combinations of various trees and crops, sometimes in association with domestic animals, around homesteads. In terms of ecological distribution, the highest concentrations of homegardens are in the humid and subhumid tropics including tropical islands of the Pacific, but they are also common in other ecological regions, especially the tropical highlands of Asia, Africa, and Mesoamerica (Nair, 1989). Excellent examples of multistory tropical homegardens with similar structure, function and species analogs are found on Java (Indonesia) (e.g., Talun-Kebun, Pekarangan), India (Kerala) in East Africa (e.g., Shamba, Chagga), and in Central America (e.g., Huertos Familiares) (Nair and Kumar, 2006) (Fig. 2).

Species complexity in homegardens is anthropogenic, a result of deliberate attempts and meticulous selection and management by farmers to provide the products they consider are important for their subsistence and livelihood (Nair, 2006). Homegardens are reputed among the oldest forms of land use activity (next only to shifting cultivation) that has evolved through generations of gradual intensification of cropping in response to increasing human pressure and the corresponding shortage of arable lands. The Javanese homegardens of Indonesia and the Kerala homegardens of India have evolved over centuries of cultural and biological transformations and represent the accrued wisdom and insights of farmers who have interacted with environment, without access to exogenous inputs, capital, or scientific skills (Wiersum, 2006).

Fig. 2 Global distribution of homegardens (Nair and Kumar, 2006).

In most high-rainfall areas of the Americas and Asia, trees are an integral part of the agroecosystem and they form the key physical feature of the local natural environment (Ewel, 1986; Perfecto and Vandermeer, 2008). Coffee and cacao have long been produced under the shade of trees in Mesoamerica and South America and consequently traditional coffee and cacao farms are indistinguishable from native forest when viewed from a satellite (Götz and Harvey, 2007).

Components of the System

Homegardens contain a mix of annual food crops with frequently harvestable tree crops that provide food and sometimes cash income. They represent a confluence of human ingenuity with ecological ambience, offered by year-round growing seasons and the amenability of the various species to grow under shade in mixed stands. In the most widely studied homegarden systems in South—and Southeast Asia, homegardens are used to produce products with high nutritional value (proteins, vitamins, minerals), medicinal plants and spices, firewood, and sometimes also forage crops and construction wood (Wiersum, 2006).

High levels of species diversity are common to all homegardens. Food plants (food crops and fruit trees) are the most common species in most homegardens throughout the world. This underscores the fact that food- and nutritional security is the primary role of homegardens—a point noted throughout homegarden literature (Brownrigg, 1985; Fernandes and Nair, 1986). Next in importance to food crops are cash crops, and with increasing trend toward commercialization, the interest in such crops is likely to only increase.

Deliberate selection and management of trees (domestication) by humans that has been going on for millennia in agroforestry systems (Simons and Leakey, 2004). Leakey et al. (2005) present evidence that subsistence farmers have domesticated locally popular indigenous fruits (*Dacryodes edulis* and *Irvingia gabonensis*) in Cameroon and Nigeria. Much of this in situ domestication has taken place in homegardens. Similar patterns of domestication have happened for other plant species in homegardens around the world, especially in those with long history as in South- and Southeast Asia (Wiersum, 2004). The global extent of homegardens is reported to include 5 million ha of land in Indonesia, 0.5 million ha in Bangladesh, 1 million ha in Sri Lanka, and 1.4 million ha in Kerala, India (Kumar and Nair, 2004).

Over the past forty years, traditional homegardens have been subjected to further scientific development throughout the globe and are currently referred to as multi-strata agroforestry. Coffee (*Coffea* spp.) cultivation covers 11 million hectares, involves 10 million farmers yielding 22 million tons of green coffee annually. Coffee production impacts the livelihoods of 125 million people. Cocoa (*Theobroma cacao*) cultivation covers 10.2 million hectares, includes 10 million cocoa farmers who produce 4.5 million tons annually. Cocoa production impacts the livelihoods of 40–50 million people. Globally, almost 50% of coffee and 30% of cocoa is cultivated under shade in multi-strata agroforestry systems by smallholder farmers (Somarriba and Lopez-Sampson, 2018). In addition to these crops, many other well-known perennials, such as black pepper (*Piper nigrum*), vanilla (*Vanilla fragrans*), along with lesser-known crops including Yerba mate (*Ilex paraguariensis*) and cupuazú (*Theobroma grandiflorum*) are typically grown under shade trees in multi-strata agroforestry systems (Somarriba et al., 2001). Multi-strata agroforestry systems help to address SDGs by providing environmental integrity, carbon sequestration, biodiversity conservation, economic valuation of intangible benefits, and social equity. In terms of complexity and species diversity, homegardens and multi-strata agroforestry systems represent

a unique set of ecological sustainability characteristics of natural systems as well as production benefits of agricultural systems. Nutrient cycling within multi-strata systems, a consequence of species diversity, further benefits ecological sustainability (Nair and Kumar, 2006).

Temperate Zone Anthrome (Silvopasture, Alley Cropping—Silvoarable)

Large parts of North America and Eurasia have similar biomes. All of these areas share similarities in precipitation, temperature, elevation and latitude. The Eastern USA along with parts of Eastern Canada, Western Europe, a large part of Eastern China, Korea and Japan contain large areas of the temperate broadleaf and mixed forest biome (Whittaker, 1975). In addition, the temperate broadleaf and mixed forest biome is found in Australia, New Zealand, Chile and Argentina. These biomes are dominated by broad leaved deciduous trees but also containing conifers. The temperate broadleaf and mixed forest biomes Temperature deciduous forests occur in mid-latitudes where cool winters, warm summers, and high year-round precipitation occurs. These regions have long growing seasons (4 to 6 frost free months) and precipitation either distributed evenly throughout the year or peaking in the summer (Walter, 1985) (Fig. 2).

China has practiced agroforestry for many centuries (You, 1991; Zhu et al., 1991). Orchards and mixed farming agroforestry practices were widely utilized throughout many parts of Europe from Roman times up to World War II (Lelle and Gold, 1994; Eichhorn et al., 2006). Historically, Native Americans, across what is now the United States and Canada, have been practicing indigenous forms of what could be termed landscape-scale agroforestry for millennia (Rossier and Lake, 2014). In Europe and elsewhere, specific differences arise due to a patchwork of many countries, each with different land use practices and traditions in agriculture, forestry, and agroforestry (Eichhorn et al., 2006; Dupraz et al., 2018).

Five agroforestry systems are commonly found in the USA and Canada, and of these five, two are commonly found across most regions of the temperate zone. Due to climatic similarities across temperate regions, combined with related economic infrastructure, alley cropping (silvoarable) and silvopasture practices are common throughout the temperate zone (Gordon et al., 2018). Temperate zone agroforestry is defined as: intensive land-use management that optimizes the benefits (physical, biological, ecological, economic, and social) from biophysical interactions created when trees and/or shrubs are deliberately combined with crops and/or livestock (Gold and Garrett, 2020).

As mentioned, two agroforestry systems in particular, silvopasture and alley cropping (silvoarable) are common to all areas of the temperate zone (Gold and Hanover, 1987).

Alley Cropping (Silvoarable)

A key advantage of food-producing agroforestry systems is that they are more resilient to climate stressors than are annual cropping systems. Compared to temperate zone annual crop monoculture production practices, integrated tree and crop practices, that is, alley cropping, can increase land use efficiency through improved overall yields compared to separate production of trees and crops in monocultures (Wolz et al., 2017). Agroforestry systems can diversify farm portfolios, spread risk and increase both the economic and environmental resilience of farms (Krebs and Bach, 2018). In addition, alley cropping can increase ecosystem resiliency by buffering against weather extremes, diversifying income as a hedge against financial risk, increasing biodiversity, reducing soil erosion and improving nutrient- and water-use efficiency (USDA-FS, 2017).

Alley cropping (silvoarable) systems consist primarily of timber, nut or fruit trees intercropped with arable crops. Alley cropping systems combine trees planted in single or multiple rows with agricultural or horticultural crops cultivated in the alleyways between the tree rows. When specialty crops such as herbs, fruits, vegetables, nursery stock, or flowers are grown in the alleys, the microclimate created by the trees enables the economic production of these sensitive high-value crops in stressed environments.

In the USA, high-value nut or acorn-producing hardwoods such as walnut (*Juglans* spp.) (Scott and Sullivan, 2007; Cardinael et al., 2015), chestnut (*Castanea* spp.) (Wilson et al., 2018), pecan (*Carya illinoensis* (Wangenh.) K. Koch.) (Kremer and Kussman, 2011), hazelnut (*Corylus* spp.) (Molnar et al., 2013) and oak (*Quercus* spp.) (Eichhorn et al., 2006) are the favored species in alley cropping practices (Gold 2019). Typical intercrops include corn, soybean, winter wheat and oats (Wolz et al., 2017).

In the United Kingdom, silvoarable agroforestry (alley cropping) often takes the form of orchard intercropping with fruit trees or nut trees and involves a horticultural component in either the understory or the overstory. Tree rows provide income from the fruit (e.g., apples, pears, cherry), nuts (walnut, hazelnut, chestnut) and cropped alleys provide annual income. Intercrops include cereal commodity crops along with horticultural and/or root crops (Newman et al., 2018).

Intercropped fruit orchards are found in many parts of Europe. The total area is estimated to be around 1 million hectares in 11 countries stretching from northern France, Switzerland, Austria through Germany and reaching up to northern European countries including Poland and Denmark (Herzog, 2000). In Europe, on the alluvial terraces of the Isère river new walnut plantations are intercropped with maize for the first years. It is sown very close to the trees, which stimulates tree height growth and restricts side-branching. Walnut growers follow the maize with winter wheat or barley for several seasons, which gives more space for the trees and makes it easier to prune them following the nut harvest (Mary et al., 1998).

Historically, in Italy, crops were very commonly planted among trees of various species in fields. Trees included fruit trees or olive plantations, or trees like ash, maple (*Acer* spp.) and elms. They were used as trellis for grapes and would also provide forage

and biofuel for fires and ovens and twigs for basketry. When fields were not sown with cereals or forage crops they would be grazed. At present, olive plantations are intercropped with cereals or forage crops, as olive plantations are long lived wide spacing between trees. Research on modern olive alley cropping systems combines olives with other crops, and uses chickens to weed and fertilize the trees and the crop (Rosati et al., 2009).

In the temperate region of China, alley cropping systems based on paulownia (*Paulownia* spp.) intercropped with grains (e.g., winter wheat), oil crops, vegetables, medicinal herbs and melons are the most commonly practiced agroforestry systems. In addition, Chinese date (*Ziziphus jujuba*) intercropped with agricultural crops has a long history and is widely practiced. Intercropping with apple (*Malus* spp.), peach (*Prunus persica*) and pear (*Pyrus* spp.) has also been widely adopted since the 1970s and intercropping of crops with ginkgo (*Ginkgo biloba*), or maidenhair trees, has also been developed (Chang et al., 2018).

Silvopasture

Silvopasture systems involve the use of timber, nut, or fodder trees with pasture and/or range and livestock (e.g., cattle, sheep, goats) using managed intensive rotational grazing practices. Integrating trees, forage crops, and livestock creates a system that produces a constant flow of marketable products while maintaining long-term productivity. Economic risks are reduced because livestock and forest components require different inputs, share few common diseases and pests, and sell into different markets. In addition, silvopasture systems are visually desirable within rural landscapes. There is evidence that humans have an evolutionary predisposition to prefer savanna-type landscapes to forests (Balling and Falk, 1982). Integrated forest grazing systems often have a normal forest structure and an open grassy understory similar to early successional plant communities of native forests. Rows of pruned pine trees in silvopastures with a well-groomed pasture understory are open and park-like.

Given the widespread co-occurrence of grazing and forestry across North America, intensive and integrated production of livestock and tree products is the most prevalent form of agroforestry found in the United States and Canada. The most commonly practiced forms of silvopasture in North America are integrated forest grazing and silvopastures. Integrated forest grazing uses livestock to harvest native forest plants as part of a planned forest ecosystem management system. Private land holdings in the eastern and central portions of the United States often include woodlots or non-industrial forests which are grazed by livestock. The largest blocks of grazed, privately-owned industrial and non-industrial forests are found in the southern and southeastern United States (Pent et al., 2020).

Silvopasture has been common in Europe since the Neolithic period to graze sheep, goats, pigs and cattle both within forests and on wood pastures outside the forest (Pinhasi et al., 2005). This is still common in many parts of Europe. Historically, a wide range of species were retained in wooded pastures, with species producing edible fruits being most common. Species included oaks (*Quercus* spp.), beech (*Fagus* spp.), lime (*Tilia* spp.), ash (*Fraxinus* spp.), sycamore (*Acer pseudoplatanus*), chestnut (*Castanea sativa*), hornbeam (*Carpinus* spp.) and some fruit trees (pear (*Pyrus* spp.), cherries and plums (*Prunus* spp.), apple (*Malus* spp.)). Trees were often left in pastures and agricultural fields, where they did not interfere with manual cultivation techniques and provided shelter and feed for animals (Hartel et al., 2015).

The southern beech, (*Nothofagus antarctica*) one of the main deciduous native species in Patagonia, Argentina, covers ~750,000 hectares. This region is where much of the silvopastoral activity is concentrated. Roughly 70% of native southern beech forest in Patagonia has been used as silvopasture systems. Sheep and cattle are the primary livestock species grazed under the southern beech (Peri et al., 2018).

Components of the System

Similar to the situation in tropical biomes, temperate agroforestry systems share “key agroforestry ideotype combinations” where functional attributes of the components (i.e. mixtures of deep- and shallow-rooted tree species, legumes and non-legumes, etc.) are similar across the temperate zone.

Alley Cropping

Alley cropping can be viewed as recreating the structure of a savanna in an agroforestry system with multiple canopy layers consisting of a design that contains an overstory of nut trees, mid-layer of fruiting small trees and shrubs, and a groundcover of annual crops or perennial grass groundcover. In nut-based agroforestry systems, crops grown in the alleys between tree rows provide annual income while the longer-term nut crop matures. Primary agroforestry and alley cropping design criteria include imitation of the structure and function of natural ecosystems with species that generate an economic yield to support the farmer (Krebs and Bach, 2018).

Growers planning to farm between tree rows need to think about the width of their alleyways. Between-row spacing is primarily determined by machinery width, mature size of nut tree species, with secondary considerations for sunlight requirements of the alley crop. With closer spacing, the intercrop grown in the alley will encounter light competition at an earlier age, requiring a more rapid change to shade-tolerant intercrops (Wilson et al., 2018). Wider spacing makes intercropping easier but delays the fullest realization of economically viable nut crop yields.

Recommended principles for designing the cropping system based on this approach include selecting species for complementary functional traits, developing complex trophic levels and reproducing ecological succession (Malézieux, 2012). Trait-based agroecology has emerged as one of the dominant paradigms in terrestrial ecology (Martin and Isaac, 2018). Studies that evaluate the complex linkages between functional traits, functional diversity and ecosystem functioning have recently begun to explore concepts surrounding “multifunctionality,” the idea that multiple ecosystem functions should be considered as a management goal. Multifunctionality has clear implications for trait-based agroecology and for agroforestry, where land managers manipulate on-farm diversity to enhance ecosystem services beyond yield alone (Finney and Kaye, 2017).

Silvopasture

Silvopasture is an agroforestry practice that intentionally integrates trees, forage crops, and livestock into a structural system of mutually supportive planned interactions. These interactions are managed intensively to simultaneously produce wood or non-timber forest products, high quality forage, and livestock on the same land unit in an environmentally sustainable manner. The forage component may be either native forage plants or introduced species managed as an improved pasture. This more intensive approach to land use provides the foundation for integrated commercial timber and livestock production systems (Pent et al., 2020).

While alley cropping combines two components, trees and crops, silvopasture deliberately integrates three components: trees, understory vegetation, and domestic livestock. Trees and livestock are combined with improved pasture plants to form carefully designed systems that integrate intensive animal husbandry, silviculture, and forage agronomy. Livestock become tools for managing forest trees and their understory plant communities for multiple outputs or outcomes, including timber, forage, wildlife habitat, fire fuels reduction, and improved water quantity and quality. Skillful selection of forage plants and manipulation of micro-environments within silvopastures can result in high quality green feed available for livestock, while providing them with shelter during inclement weather (Pent et al., 2020).

Most ruminant livestock species are viable candidates for temperate zone silvopasture including cattle, sheep and goats. Chickens are also an option. Pigs must be very carefully monitored to avoid damage to trees and understory forages. There are two main approaches to silvopasture systems: (1) Establishing trees within existing pasture lands; (2) Thinning native forest stands to support the growth of pasture for forage (Gold and Garrett, 2020).

Understanding the phenology and morphology of tree and grass species, or their growth over time, can aid in the selection of complementary components of a silvopasture system and the proper management of competitive tree-forage interactions. Silvopasture influences ecosystem processes of hydrology, nutrient cycling, energy flow, and succession primarily through manipulation of community structure. The basic strategy combines trees, forages, and livestock such that each component produces usable products and contributes to stability and conservation of land resources. These systems also can contribute to enhanced aesthetics and outdoor activities. While management intensity may be high, silvopasture systems require lower external inputs of nutrients or pesticides than open pastures (Pent et al., 2020).

Arid/Semi-Arid Tropical Anthrome (Improved Fallows, Farmer-Managed Natural Regeneration, Evergreen Agriculture)

In the semi-arid and sub-humid zones of West Africa, known also as the savanna woodland biome, farmers have for many generations maintained a traditional land-use system, known as the agroforestry parklands system, which is characterized by the deliberate retention of trees on cultivated or recently fallowed land. Trees are an integral part of the system, providing food, fuel, fodder, medicinal products, building materials and saleable commodities, as well as contributing to the maintenance of soil fertility, water conservation and environmental protection (Boffa, 1999).

The savanna woodland biome occurs widely in tropical and subtropical regions including some Caribbean islands, Brazil and northern Argentina, east and central Africa, portions of India and China, northern and eastern Australia. Compared to the more mesic tropics, it is found where the dry period is more prolonged and the annual rainfall is less than in true closed forest. Trees are widely scattered, usually leafless during dry season and vegetation is usually rich in herbs (especially grasses). Trees are commonly stunted to the size of tall shrubs, usually less than 60 feet high at best with flattened crowns. Many of the trees belong to the legume family (Fabaceae) (Boffa, 1999).

Improved fallows and farmer-managed natural regeneration (FMNR) are practiced widely across sub Saharan and other semi-arid regions of Africa, India, the Caribbean, Mexico and Central America. In particular, in many parts of Sub Saharan Africa, farmers use improved fallows as a strategy for improving soil fertility within a shorter time-period, compared with natural fallow. Improved fallows are an agroforestry technology consisting of planting legume tree and/or shrub species in rotation with cultivated crops. These improved fallows contribute to food security, climate change mitigation and adaptation, and sustainable conservation of natural resources (Partey et al. 2017). When the fallow period ends, trees, shrubs, and/or herbaceous legumes are cut down or coppiced and the resultant biomass (leaves, twigs, branches) is incorporated into the soil while the land is prepared for the following crop. Legume species improve the soil through biological nitrogen fixation in which recycled nutrients are deposited through litter or when biomass is harvested at the end of the fallow period and incorporated into the soil. Improved fallows are

recognized as cost-effective and a viable alternative to inorganic fertilizers. Evidence of improved soil fertility and increased crop productivity with improved fallows have been observed across sub-Saharan Africa (Partey et al. 2017).

The most well described and widely promoted agroforestry practice in Sub Saharan Africa centers on *Faidherbia albida*. Over 60 years ago scientists observed that farmers throughout the Sahelian region of Africa were retaining their *Faidherbia* trees in their sorghum and millet fields (Barnes and Fagg, 2003). The species has long been an integral part of Sahelian agriculture, where farmers have nurtured and protected the trees growing in their fields for centuries. The trees are a frequent component of the farming systems of Senegal, Mali, Burkina Faso, Niger, Chad, Sudan, and Ethiopia, and in parts of northern Ghana, northern Nigeria, and northern Cameroon (Boffa, 1999). There are many reports of substantial increases in the grain yield of unfertilized millet grown under *Faidherbia* in West Africa (Barnes and Fagg, 2003). Increases in yield have also been reported for sorghum grown under *Faidherbia* in various parts of Ethiopia, other parts of Africa, and in India. The deliberate expansion and promotion of the traditional *Faidherbia* agroforestry system is currently known as Evergreen Agriculture, defined as the integration of selected tree species into annual food crop systems (Garrity et al., 2010).

The use of farmer-managed natural regeneration (FMNR) has enabled a major “regreening” to take place in the Sahel in recent decades. In southern Niger alone, following two decades of drought and famine in the 1970s and 1980s with massive losses of crops and livestock, human outmigration and mortality, over 5 million hectares of farmlands have “regreened” (Pye-Smith, 2013). This has improved crop and livestock productivity and enhanced the resilience of these agricultural systems to drought and temperature extremes in the face of climate change. The practice of FMNR of trees on farmlands is accelerating across the Sahel. At present, trees occupy 16% of the total area of croplands in the semi-arid and subhumid zones of the Sahel (Brandt et al., 2018), and 23% in the West Africa savannas. Nearly 100% of this tree cover is a result of the practice of FMNR by the millions of small-scale farmers of the region. FMNR has also gained in popularity in many dryland areas in western, eastern and southern Africa (Brandt et al., 2018).

Components of the System

Incorporating improved fallows includes the addition of fertilizer trees into the agricultural landscape. The term “fertilizer trees” is commonly used to refer to the utilization of N-fixing leguminous trees in cereal production systems to improve the availability of N to crops. Included among the widely used fertilizer trees in Sub-Sahara are acacia (*Acacia* spp.), albizia (*Albizia* spp.), calliandra (*Calliandra calothyrsus*), erythrina (*Erythrina* spp.), faidherbia (*Faidherbia albida*), flemingia (*Flemingia* spp.), gliricidia (*Gliricidia sepium*), inga (*Inga edulis*), leucaena (*Leucaena* spp.), and sesbania (*Sesbania* spp.) (Sileshi et al., 2014). Impacts include restoration of soil fertility and promotion of the biological processes and ecological functions that, taken together, rehabilitate degraded land and increase crop yields. In terms of increased crop yields, synergistic effects of synthetic fertilizer and fertilizer trees have been documented. Substantial yield increases from fertilizer trees have been demonstrated with many crops including maize, millet and sorghum even at 25–50% of the recommended dosages of synthetic fertilizer. Key to the success of improved fallows are nutrient cycling, increased availability of macronutrients (extractable N, P, and K), cations and improvement in soil pH, increased organic matter (SOM), enhanced biological activity, improved soil physical properties, and better water relations (Sileshi et al., 2014).

In Evergreen Agriculture, vegetative soil cover is maintained throughout the year by the deliberate intercropping of trees in order to sustain a green cover on the land throughout the year. This approach increases nutrient supply through nitrogen fixation and nutrient cycling, generates increased quantities of organic matter in soil surface residues, improves soil structure and water infiltration, enhances carbon storage both above- and below-ground, induces more effective conservation of above and below-ground biodiversity and increases the direct production of food, fodder, fuel, fiber and income from products produced by the intercropped trees (Garrity et al., 2010).

Farmer-managed natural regeneration (FMNR) involves identifying and protecting the naturally regenerating seedlings of trees and shrubs that establish themselves on farmlands. It is dependent upon the presence of living root systems and seeds. Shoots from existing roots grow more rapidly than saplings from seed because of better- and well-established root systems, and make up the bulk of the protected woody stems on farms in southern Niger. Farmers generally choose one to five of the strongest stems from stumps they wish to retain on their land and pruning away the remainder. These stems are managed to grow into full canopy trees that can be harvested to provide fruits, medicine, gum, oil, firewood, timber. In addition, they provide foliage used as fodder for meat and milk production, tree nectar for honey, and tree leaves as biofertilizers for improved soil health and crop production. Favored species vary from place to place along with the density of the trees in the crop fields with densities ranging from 40 to 150 trees per hectare (Garrity and Bayala, 2019).

Species commonly found in FMNR in the African drylands include the baobab tree (*Adansonia digitata*), which provides nutritious fruits and leaves; the shea tree (*Vitellaria paradoxa*) that provides butter used in cooking, in chocolate and cosmetics; gum arabic (*Acacia senegalensis*) that provides a gum used in many food items; and as previously mentioned, *Faidherbia albida*, which enriches soils and provides valuable pods and foliage for fodder (Garrity et al., 2010). Trees on farmlands provide another significant stream of benefits including soil and water conservation and a more favorable microclimate for crops to withstand wind and heat and drought stress (Bayala et al., 2014).

Summary

Agroforestry incorporates an array of successful strategies that already exist across the globe spanning many biomes (Nair et al., 2017; Van Noordwijk et al., 2019a). Biodiversity-based management of working lands, including agroforestry, has been practiced since ancient times and their value has been recognized, updated and promoted across our global biomes over the past forty years. Some of these management systems, such as home gardens, indigenous use of fire, selective retention of array of trees, shrubs, food and medicinal crops no longer exist in their original form, whereas others, such as silvopasture and multi-strata farming systems, persist in many different biomes. These biodiversity-based working land management practices are knowledge, rather than technology, intensive (Wiersum, 2004). Agroforestry systems, multifunctional land management strategies found throughout the world across temperate and tropical biomes, represent a major opportunity to ensure sustainable production of food and fiber along with the ecological heritage of the planet (Ellis, 2013; Nair et al., 2017; Kremen and Merelender, 2018; Udawatta et al., 2019).

Abstract

The Pampas plains were originally covered by grassland communities modulated through the millennia by a combination of rainfall, temperature and small topographic gradients. The anthropic intervention historically modified pristine structures and functions giving rise to a novel ecosystem that was reoriented to produce food, fiber and bio-energy. From the beginning of the 20th century, the quick expansion of agriculture on natural lands and the intensification of agricultural practices triggered big ecological changes that altered the stocks and fluxes of carbon and the hydrological processes as well. Carbon and water were closely linked to the provision of habitat for biodiversity and the supply of regulation ecosystem service. Inevitably, ecological functions associated with carbon and water were profoundly modified the anthropic intervention, but conservation practices and technology incorporation in the last decades smoothed and even reversed the most outstanding negative trends. It is well known today that a return to the pristine condition will no longer be possible in the Argentine Pampas because of social and economic reasons, but an adaptive, science-based management helps maintaining the agricultural productivity preserving at the same time novel biodiversity assemblages and new configurations of ecosystem service provision.

Should the Pampas Be Considered a Novel Ecosystem?

Human activities have deeply altered land cover patterns through conversion to croplands and pastures (Tilman et al., 2001; Foley et al., 2005; Ellis et al., 2010) particularly affecting temperate grasslands worldwide (Ramankutty et al., 2008). The Argentinean Pampas biome has not escaped this conversion. In 1774 Thomas Falkner described the Pampa as “One immense sea of grasslands, with scattered forest islands...” (Ghera and León, 2001). With this statement he transmitted the perception of the native inhabitants and the reasons why this landscape is named “Pampas” (in the natives’ language Quechua “Pampa” means “uniform extensive plain”). Since then, Pampean grasslands have been severely modified by human activities.

Taking advantage of the diversity of soils, climates and landscape, these transformations of the vegetation and the use of land occurring in the Pampas biome were extended to the bordering biomes. In this sense, it is convenient to distinguish those changes of wide geographical distribution such as deforestation and establishment of agricultural crops in dry forests of the Chaco and Espinal along with the progress of livestock. This plays an important role on the services provided by their ecosystems (Jobbagy, 2011). Only small corridors of remnant grassland survive within the matrix (Bilenca and Miñarro, 2004). Hence, grassland fragmentation (Baldi et al., 2006), plant invasions (Poggio and Mollard, 2010) and reductions in area of remnant grassland (Burkart et al., 2011) may lead to the generation of novel ecosystems (Hobbs et al., 2013). This diversity of ecological land cover patterns created and sustained by human populations also links human and natural systems (Ellis and Ramankutty, 2008). This is most relevant in novel ecosystems, like the Pampas agro-ecosystem where new combinations of species and abiotic conditions make the outcome of management even less predictable (Hobbs et al., 2013).

The Pampas biome is a 60 Mha plain located in the center of Argentina between 57°W and 68°W and 28°S and 40°S (Fig. 1). Several subunits are recognized based on geomorphology, drainage, geology, physiography, soils and vegetation (Cabrera, 1951; Soriano et al., 1991).

The Pampas are climatically considered as a warm temperate region, with a mean temperature ranging from 14 °C in the South and the isotherm of 18 °C delimiting the North, and humid, with annual rainfall ranging from 500 mm in the West to 1200 mm in the East (FAO, 2006). This region has shown a significant change in precipitation in the last century (Giorgi, 2002) with an increase

in annual values from the 1960s (Minetti et al., 2009). Furthermore, the increase has been particularly marked near the western margin of the Pampas, displacing westward the transition to semi-arid regions that represent the boundary of rainfed agriculture (Viglizzo et al., 1995). Nevertheless, there is still a considerable uncertainty about the future climatic conditions.

The region is considered a hyperplane (Jobbagy et al., 2008), a flat or slightly rolling with Mollisols as predominant soils (Moscatelli, 1991), formed on loess-like materials (Alvarez and Lavado, 1998). Because of the eolian origin of sediments from Southwest to Northeast and the climatic rainfall gradient from West-East, the depth and texture of soils varies from shallow and sandy in the West to deep and clayed in the East (Alvarez and Lavado, 1998; Berhongaray et al., 2013). The predominant clay mineral in the region is illite (Alvarez and Lavado, 1998). Within the upper 1 m of the soil profile a petrocalcic horizon appears in many soils along the West and the South ends of the region (Teruggi, 1957). Soil organic carbon is strongly associated to rainfall (Berhongaray et al., 2013). Conversely, soil pH is not climate regulated, with a range from 6 to 9, and no signals of acidification by cultivation have been detected (Berhongaray et al., 2013). High pH values are usually associated to hydromorphic lands (Hall et al., 1992).

This anthrome supports one of the largest temperate grasslands on the globe and has undergone major changes since the 16th century on it (Matteucci, 2012). A traditional plant vegetation approach defined the Pampas as a vast of humid and sub-humid grassland (Baldi and Paruelo, 2008) in which graminaceous species predominate, with some minor areas occupied by natural forest that cover 7% of the total surface (Cabrera, 1994). Ecologically, the Pampas is limited in the northern and western margin with the eco-region of Espinal. The Espinal portion extends irregularly from the center of province of Santa Fe, northeastern Córdoba and northern Entre Ríos and supports remnant xerophilic woodlands dominated by *Prosopis*. These woodland remnants are isolated and immersed in an agricultural matrix.

Originally, only small groups of indigenous nomadic people inhabited the area before Europeans brought horses and cattle by the mid-16th century. While the indigenous people had probably used fire to facilitate hunting, it is assumed that both the fire and grazing regimes would have changed greatly since the introduction of livestock as well as the use of fires to herd the cattle and horses around 1600 (Soriano et al., 1991). The Pampas grasslands have experienced an especially high increase in agricultural production (Baldi and Paruelo, 2008), particularly of soybean since the 1990s, bolstering Argentina's role as a world-leading agricultural producer (Baumann et al., 2016). Today, the largest areas are sown with soybean as summer crop and wheat as winter crop followed by oats, corn, sunflower and natural or semi-natural grassland under cattle grazing (Lara and Gandini, 2014). Around 90% of the national grain production is carried out in this region.

While croplands occupy about 85% of the mosaic area, anthropic elements such as fencerows, roadsides, and woodlots, homesteads, water bodies and abandoned land, each one covering less than 1% of the remaining surface, which sustain most of plant diversity in agro-ecosystems, particularly native plants (Ghersa et al., 2012; Poggio et al., 2015). Water bodies and woodlots of foreign trees, a novel element introduced 150 years ago in the Pampas, are used as wind barriers occupying 0.2% of the area and are important drivers of bird and arthropods richness and abundance (Ghersa et al., 2012; Poggio et al., 2015). At the same time, this has triggered widespread loss and fragmentation of natural vegetation (Viglizzo et al., 2010) and an increasingly replacement of grazing land cropland (Gavier-Pizarro et al., 2012).

Historical Drivers of Landscape Change

The change in land use and cover through agricultural expansion (Goldewijk et al., 2017) and intensification through the increasing use of technology and external inputs, such as high yield crop varieties, fertilization, irrigation or pesticides (Adhikari et al., 2018),

have been the main historical drivers of changes in the world's biomes. Lands with agricultural aptitude in Argentina were no exception to this global trend. Regional change occurred both in terms of conversion of land for cultivation, as in the gradual intensification of agriculture (Viglizzo et al., 2011; Piquer-Rodríguez et al., 2018).

The Pampas, originally characterized by a treeless grassland where vegetation heterogeneity was determined by topographic and climate gradients, has a longer land-use history. Cattle ranching started in the 16th century with the arrival of the first European settlers (Giberti, 1954) and grazing became the main regulator of the structure and functioning of the native grasslands (Soriano et al., 1991). Due to the lack of fences protecting crops from grazers, workers and transportation, during the first centuries of colonization crops were cultivated only at small scales near villages (Sbarra, 1964). According to official records, the cropped area expanded since the end of the 19th century (Fig. 2, see Multimedia Video 1 in the online version at <https://doi.org/10.1016/B978-0-12-409548-9.12060-3> annexed) in response to the massive immigration, the spread of wired fences and the expansion of the railway network (Hall et al., 1992). Nowadays, the Pampas were mostly converted to cropping and pasture-based grazing areas. The modification of the landscape and the introduction of new organisms caused the creation of novel ecosystems (Viglizzo et al., 2001; Satorre, 2005).

Agricultural expansion was fast in the humid areas and slow in the sub-humid and semiarid ones. Rainfed crops were cultivated where annual rainfall is above 600 mm, on well-drained soils. Hydromorphic soils were used for grazing. The cultivated area increased 45% between 1990 and 2006, then expanding outside the Pampas regions. One-half of the cultivated lands was allocated to genetically modified soybean crops (Leguizamón, 2016). Currently 60% of the Pampas is under annual crop production, with soybean (*Glycine max* (L.) Merr.), wheat (*Triticum aestivum* L.), and maize (*Zea mays* L.) as major crops (Viglizzo et al., 2011).

The Pampas represented a large scale, long-term, and non-controlled experiment of low input farming (Viglizzo et al., 2001) until the 1990s, referring to systems that use reduced quantities of inputs such as fertilizers, agro-chemicals, irrigation, machinery, etc. (Matson et al., 1997). Nevertheless, since the beginning of the 1990s, the spread of an increasingly soybean-dominated agriculture was supported by no-tillage (Nocelli Pac, 2018), double soybean-wheat cropping, cover crops, and the increasing use the low-cost fertilizer and pesticide inputs (Gavier-Pizarro et al., 2012; Andrade et al., 2017; FAOSTAT, 2019), which allowed intensified cultivation schemes. As a result, the production of the main crop commodities in the region was quadrupled during the last 50 years (Fig. 3) (Secretaría de Agroindustria, 2019), allowing a more efficient use of water and nutrients in comparison to cultivation before the 1960s (Andrade et al., 2017; Piquer-Rodríguez et al., 2018). In particular, no-till gained ground quickly, and was an effective solution to the problem of soil organic matter loss due to erosion as it leaves a greater percentage of soil covered with plant residues (Fu et al., 2006). It meant to keep soil in its place and mainly keep the top layer which is the most fertile fraction. In line, because of fossil-fuel savings, no-till adoption drastically reduced greenhouse gases (GHGs) emissions (Neufeldt et al., 2015). The combined effects of those technologies explained yield increases in main crops (Fig. 4) reflected in the patterns of crop yield growth, stagnation, and collapse (Ray et al., 2012).

Fig. 4 Crop yield trends over the period 1961–2008. The trends were divided into the six categories and color coded. Maps show only those areas in the political unit where the crop was harvested. Own elaboration from Ray, D. K., Ramankutty, N., Mueller, N. D., West, P. C., and Foley, J. A. (2012). Recent patterns of crop yield growth, stagnation, and collapse. *Nature Communications*, 3, 1293.

The expansion of wheat, corn and sunflower in the 20th century, and the expansion of soybeans in 1990s displaced most ranching activities into the Espinal biome (Modemel et al., 2016; Viglizzo et al., 2011). Thus, large portions of natural lands historically used for cattle grazing were converted to row-crop production (Baldi and Paruelo, 2008). That conversion was probably strengthened by the outstanding adoption of technology innovations in crop production in contrast to technology incorporation in livestock production, which still remained relatively stagnant.

Carbon and Water Dynamics in the Pampas

GHGs Emissions and Carbon Balance

The rapid conversion of land affected bio-geochemical processes in general and the balance of GHGs in particular. The carbon balance can vary strongly when the analysis is scaled down from the region and the country to the agricultural system. For a comparative purpose, Figs. 5 and 6 show average estimates of carbon balance (emission minus sequestration) in livestock and crop production activities.

There are great variations between the compared systems. With the exception of extensive production schemes, livestock systems clearly tend to show higher emission rates per hectare than the crop production ones. Then, while the carbon balance tends to be positive in extensive, and negative in intensive cattle production systems, the negative balance tends to predominate in crop production systems with a probable exception in the case of high-yielding maize. However, setting aside the irrigated rice production (which shows high rates of carbon emission), it should be noted that the negative balance of crops is significantly less important than that of intensive livestock systems.

The carbon balance of the whole agricultural system will depend on the combination and proportion of land allocated to different farming activities. In the case of soybean, its rotation with agricultural activities that show higher capacity to sequester carbon will generate integrated systems with GHG emission levels that are lower than those of soybean monocultures. This notion may become relevant when farmers try to evaluate and certify production activities in terms of their carbon balance. A diversified production scheme where crops rotate may benefit the production system as a whole.

Carbon Losses and Gains in the Pampas Soils

When the natural vegetation is removed for cultivation, there is a decrease in the soil organic carbon content, which was observed in the soils of the Pampas. That loss of soil carbon was greater in early years and was greater in the soils of the humid portion, with high original soil carbon content, than in the soils of the semiarid portion, with less soil carbon content (Fig. 7). The causes of the decrease in the soil carbon levels were the soil erosion and the negative carbon balance between the carbon inputs from crop residues and the loss of carbon as CO_2 from soil organic matter decomposition. In recent years it was observed that this tendency

Fig. 5 Estimated figures show the difference of carbon emissions, soil carbon sequestration and carbon balance ($\text{ton ha}^{-1} \text{ year}^{-1}$) between four beef production systems that differ in their intensification level. Negative figures indicate that carbon emission is greater than carbon sequestration.

Fig. 6 Estimated figures show the difference in carbon emissions, soil carbon sequestration and carbon balance (ton ha⁻¹ year⁻¹) between four crop production systems that are spread in South America. Negative figures indicate that carbon emission is greater than carbon sequestration.

Fig. 7 Soil organic carbon loss in the Pampas during 120 years of agricultural crops. L., Caride, C. and Cantet, R. J. C. (2013). Land use effects on soil carbon in the Argentine Pampas. *Geoderma* **192**, 97–110; Alvarez, R., Steinbach, H., and de Paepe, J. L. (2015). Carbono Orgánico. In Alvarez, R. (ed.) *Fertilidad de suelos y fertilización en la Región Pampeana*. 1st edn, pp. 47–91. Buenos Aires: Editorial Facultad de Agronomía.

was attenuated or reversed in the Pampas through the adoption of technology and good agronomic practices (Alvarez et al., 2015; Andriulo and Cordone, 1998). Those soils with an initial high level of soil carbon are slowing down their loss, and those with initial low levels of soil carbon are even increasing its level. Despite of the gradual reduction of perennial pasture and the higher proportion of soybean in crop rotations, the carbon inputs increased by increases in the crop yields (genetic improvement and fertilization) and due to the incorporation of the no-till as a generalized practice. Additionally, in the last decades an increase in rainfall also contributed to higher yields and carbon inputs, especially in the semiarid lands.

Soil carbon losses were similar in most sub-regions, 27%–28% reduction in soil carbon stock, except for the Southern and Flooding Pampas where losses were much lower (Fig. 8) (Berhongaray, 2010). The Flooding Pampa is a large sub-region for livestock production, where the production system is based on the use of natural grasslands. Few croplands are found in this sub-region,

Fig. 8 Soil carbon stock in natural remnants and croplands (equivalent soil mass of 3000 t ha^{-1}) of different sub-regions of the Pampa biome. Own elaboration from Berhongaray, G. (2010). *Carbono en suelos pampeanos: efectos de la vegetación y el uso*. M.Sc. Thesis. 113 p.

and land use conversion was less significant than that of the rest of the Pampas. Therefore, this sub-region remained almost isolated from annual crops expansion and this explains its small reduction in soil carbon stocks. On the other hand, despite the Southern Pampas had a land-conversion history that was similar to most sub-regions in the Pampas, its colder climate has probably prevented a higher carbon loss from soil organic matter decomposition.

When soils are converted from cultivated to permanent perennial vegetation, i.e. from crop to pasture, the soil carbon loss can be reverse (Studdert et al., 1997). Soil carbon content significantly increase after the conversion from cropland to pasture (Fig. 9). Unlike annual crops, cultivated pastures maintain a permanent cover of vegetation on the soil, reducing soil temperatures, and adding higher amount of organic matter, particularly from belowground, to the soil (Guo and Gifford, 2002). A diversified production system, with frequent conversions to pasture, could partially or fully recover the amount of carbon lost from soil during the cultivation process.

Fig. 9 Evolution of organic carbon content in soil under agriculture and in response to the inclusion of a grass-based perennial pasture. Own elaboration from Studdert, G. A., Echeverría, H. E. and Casanovas, E. M. (1997). Crop-pasture rotation for sustaining the quality and productivity of a Typic Argiudoll. *Soil Science Society of America Journal* **61**, 1466–1472.

Hydrological Processes in the Pampas Novel Ecosystems

As evapotranspiration decreased because of the replacement of perennial vegetation by annual crops, water runoff and water infiltration increased and the water table rose and approached the soil surface (Bertram and Chiacchiera, 2017). Annual crops were associated with the water-table rise (Fig. 10) because they remove less water by transpiration than trees and pastures. This has been a common phenomenon that occurs today in central Argentina mainly due to the expansion of annual crops over natural and grazing lands (Viglizzo et al., 2011; Bertram and Chiacchiera, 2017). Frequent floods in croplands of the Pampas are more associated with water-table rise and less with the increase of precipitation. In few words, floods in the Pampas are primarily explained by the water table rise and secondarily by rains. The severity of the problem increased in flat terrains with little drainage capacity.

Common sense indicates that an adaptive measure consists on working on the configuration of the system. Different species and farming activities have different potentials to remove water from the subsoil and to maintain the phreatic level at different depths. For example, wheat has a low evapotranspiration potential but alfalfa and forests show a high evapotranspiration potential. Therefore, the combination of activities with different potential to remove groundwater may play an important role to face the challenge of managing the hydrological balance of the ecosystem (Frank and Viglizzo, 2012).

The impact of the system configuration on water table depth in the Pampas was assessed between 1974 and 2008 through a model simulation process that was supported by field measurements (Nosetto et al., 2015). The authors found that the water table tends to accompany the rainfall variability, but its depth varied with farming activities. In the case of soybean monoculture, the phreatic depth tends to be close to the zero level (soil surface), but when two annual crops were introduced into the system the water table tended to move to deeper layers. When a rotation scheme with perennial pastures was incorporated into the system, the phreatic depth tended to move even deeper. This is an interesting example that shows how humans can handle the water table by modifying the configuration of the farming system.

So, looking ahead for practical lessons to ameliorate the flooding risk, the role of pasture-based livestock activities should be revalued, as well as crops and forest activities with high transpiration potential. The strategy should aim at strengthening the role of some regulatory ecosystem services that are associated with the dynamics of carbon and water in ecosystems.

Carbon, Water and Ecosystem Services

The characterization of ecosystem functioning is significant for different purposes such as biodiversity conservation and ecosystem service provision. Paruelo et al. (2001) showed that land-use influences carbon variability (in soil and biomass) throughout different seasons in the year. The amount of support, provision and regulation ecosystem services (MEA, 2005) may be decreased by decreases in net primary productivity, or C exported out of the system. Given that carbon and water interact for ecosystem functioning, a change in the carbon stocks and the carbon flows can modify the economy of water and the related ecosystem service provision (Viglizzo et al., 2016). A highly simplified picture (Fig. 11) can help understanding how water pathways were modified as humans replaced the grassy biomes in the Pampas by human-modified configurations, mostly cultivated pastures and annual crops.

In a general functional picture, part of the rainfall that follows the transpiration and evaporation pathways feed backs to clouds and rainfall. The fraction of water reaching the ground that was not evaporated nor transpired is normally known as water yield. Water yield may be divided between runoff and infiltration, providing water to the maintenance of surface streams (rivers), water bodies (lagoons, lakes) and underground aquifers. This simple functional scheme has been deeply modified by land-use/land-cover change. For example, most of the water that is reaching the ecosystem from rainfall is diverted to the evaporation pathway in

Fig. 10 Relationships between the percentage of annual crops and the water table depth in a soybean-cropping area of Central Argentina. Own elaboration from Bertram, N. and Chiacchiera, S. (2017). Fig. 11 The modification of carbon- and water-related processes by land-use/land-cover change can drastically modify both basic ecological functions and the provision of essential ecosystem services. Own elaboration from Viglizzo, E. F., Jobbágy, E. G., Ricard, M. F., and Paruelo, J. M. (2016). Partition of some key regulating services in terrestrial ecosystems: Meta-analysis and review. *Science of the Total Environment* **562**, 47–60.

a tall-grass perennial biome that had a high biomass carbon stock and was typical of the pristine Pampas. When such biome was converted into a cultivated land or simply in a bare soil with minimum plant coverage, carbon and water circuits were deeply modified, and runoff and infiltration pathways were privileged at the expense of evapotranspiration. So, trade-offs among ecosystem services were inevitable when land use and land cover were modified by anthropic interventions. Some of them such as those related to thermal and rainfall regulation were weakened in benefit of others like stream and water body maintenance and groundwater recharge (Viglizzo et al., 2016).

Concluding Remarks

Historical land-use and management change in the Pampas has irreversibly modified the biological structure and the ecological functionality of pristine ecosystems. This is the reason because the Pampas is essentially an anthrome and novel ecosystem where a restoration to the original condition is unthinkable. Driven by economic and social forces, some provisioning ecosystem services like food, fiber and bio-energy production were privileged and maximized at the expense of support and regulation services like soil formation, carbon sequestration, water regulation, soil protection and habitat provision. The replacement of the pristine by a novel agricultural ecosystem was inevitable in a fertile plain like that of the Pampas because agriculture was the basis to sustain the economy and the social development in Argentina during the last one and a half century.

Grasslands, one of the most transformed biomes of the world (Ellis and Ramankutty, 2008), have been considered highly relevant to global carbon sequestration (Viglizzo et al., 2019). As Norton (2018) argued, a science-based adaptive management is necessary to harmonize production and conservation in novel ecosystems. Various knowledge-based technologies and agronomic practices were applied to maintain novel ecosystems in the Pampas in a long-term sustainable condition: (i) spatial and temporal diversification of activities (agro-diversity), (ii) crop-crop and (iii) crop-pasture rotations, (iv) crops sequence, (v) conservation and zero tillage, (vi) cover crops (or “service crops”), (vii) fertilization and (viii) groundwater management were important to increase productivity and control carbon and water pathways. So, beyond agriculture, they were essential to maintain the habitat, the biodiversity, and the provision of ecosystem services under a novel ecological format.

Abstract

Multifunctional landscapes are typically characterized by diversified land use and complex landscape structure, thereby potentially covering many, often competing interests of different stakeholder groups. Central to the concept of multifunctionality is the assumption that this supply of a more diverse set of (market and non-market) goods leads to a number of environmental, social and economic benefits. Management strategies that increase the multifunctional use of landscapes, while sustaining natural resources for future generations, are therefore needed. Managing for landscape multifunctionality, however, requires some deep system changes, such as the collaboration between stakeholders across spatial scales and sectors as well as the transition toward more sustainable land management practices. Recently, assessments of landscape multifunctionality applying the ecosystem services framework (i.e., benefits that people obtain from nature) have emerged. In this article, we outline how such assessments have advanced our understanding of land use, which uncertainties and challenges remain to assess multifunctionality and how the valuation of multifunctionality could be used to make better informed management decisions.

Multifunctionality of Landscapes—Understanding the Concept

Multifunctionality is commonly understood as the supply of multiple ecosystem functions, services or goods within the same area (Hölting et al., 2019; Manning et al., 2018). Central to the concept of multifunctionality is the assumption that the supply of a more diverse set of (market and non-market) goods leads to a number of environmental, social and economic benefits (Foley et al., 2005). Addressing the different needs of society is essential if we are to develop sustainable and resilient landscapes that ensure the long-term protection of biodiversity and ecosystem services (O'Farrell and Anderson, 2010). In the last decades, the societal demands for achieving higher levels of landscape multifunctionality have therefore increased, in particular in connection with efforts to develop more sustainable land management strategies and to achieve increased socio-ecological resilience.

From Multifunctional to Uniform Landscapes—and Back Again?

While discussions on multifunctionality recently gained increased attention in the scientific community as well as in political agendas, multifunctionality of landscapes is not a novel concept. It has its origin in agricultural production systems which have traditionally been established and maintained to produce a multitude of different goods (Vos and Meekes, 1999). The first agricultural systems developed around settlements, where people used their environment and natural resources in manifold ways. They cultivated crops, grazed animals and used individual trees or forests in a small-scale, self-sufficient manner. Such

integrated farming-forestry systems were highly adapted to regional environmental and climatic conditions. They slowly formed characteristic landscapes throughout Europe and other human-dominated landscapes around the world, supplying location-specific sets of goods and services (Vos and Meekes, 1999).

With increasing population growth, however, the management and use of agricultural land intensified (Foley et al., 2005). Agricultural production per unit area increased substantially in the past decades due to higher inputs of land, labor, fertilizer, pesticides and feed (IPBES et al., 2018). At the same time, farms increased in size, while the diversity of cultivated crops decreased. Rural agricultural landscapes eventually transformed from multifunctional landscapes into highly specialized and rather uniform landscapes (Vos and Meekes, 1999). Due to landscape homogenization and land use intensification, interactions between ecological processes were increasingly decoupled, with severe impacts on ecosystem functions and services (Foley et al., 2005). For example, pollination rates continue to be rapidly declining due to the limited temporal and spatial availability of natural floral resources for wild pollinators and the growing use of pesticides. Likewise, soil erosion and water run-off rates are increasing due to the removal of hedgerows and other landscape elements, as a result of agricultural expansion and intensification.

In the course of these major land use changes, landscape management has become an issue of governmental planning processes and we have experienced a growing disconnection between humans and their local environment (IPBES et al., 2018). A large extent of agricultural products is nowadays part of globalized markets and decisions on what is being produced and sold at which price are made at the supra-local level, reinforcing this disconnection. Many rural areas worldwide are experiencing population declines. Smaller revenues or harder life conditions have contributed to the abandonment of these areas, leading to a continuous loss of local knowledge and place attachment (Foley et al., 2005; IPBES et al., 2018). Relational values, such as place attachment, cultural identity and moral responsibility, must be promoted again within conservation policies to strengthen the connection between humans and the environment and to contribute to the maintenance of multifunctional landscapes (Allen et al., 2018). While in many parts of the world there are virtually no landscapes left that are not shaped by humans, notions toward “multifunctional landscapes” and similar concepts such as “nature-based solutions” and “integrated agro-ecosystems,” have been picked up again, steering discussions toward increased sustainability and socio-ecological resilience (see “The Capacity of a Landscape to Supply Multiple Functions and Services: Interactions at the Landscape Scale” section) (Fischer et al., 2017; O’Farrell and Anderson, 2010).

Recent Applications and Conceptual Advancements

Linked to the idea of multifunctional landscapes, the role of interacting ecological processes and functions has always been a focal study object in ecology. In the last years, studies on multifunctionality have evolved tremendously in many fields of environmental sciences. Multifunctionality has been assessed within a broad spectrum of spatial scales and land use systems, including agricultural landscapes, urban areas, soil ecosystems, farms, forests, coastal areas, and water bodies (Hölting et al., 2019). Studies range from microbiological studies (e.g., studying the relationship between microbial diversity and functions such as nutrient cycling or organic matter decomposition; Delgado-Baquerizo et al., 2016) to the field of landscape planning, where landscape structures and functions are analyzed to better design multifunctional landscapes (Lovell and Johnston, 2009). Different methods have been developed to quantify ecosystem multifunctionality (Byrnes et al., 2014; Hölting et al., 2019) and the concept has become highly relevant in many regional planning strategies, in international legislation (e.g., Common Agricultural Policy of the European Union) and in intergovernmental organizations (e.g., World Trade Organization) (O’Farrell and Anderson, 2010). The increased use of the multifunctionality concept is certainly linked to the expected benefits in terms of biodiversity conservation, sustainability and socio-ecological resilience (see “The Capacity of a Landscape to Supply Multiple Functions and Services: Interactions at the Landscape Scale” section).

To quantify the level of multifunctionality, studies use a range of different methods to aggregate ecosystem function or service indicators into a single metric (Byrnes et al., 2014). Some studies assess multifunctionality by taking the sum or the average of all functions or services recorded. In this approach, all functions or services obtain equal weights. Other studies argue that functions or services only account to multifunctionality if they exceed a certain threshold value (Byrnes et al., 2014). These studies count the number of functions or services that are supplied above this specific threshold. Another widely-used approach is to define different weights for different functions or services, or to quantify the diversity of functions or services instead of their supply levels only (Stürck and Verburg, 2017). There is no consensus about when to use which method, as each approach has its own advantages and constraints (summarized in Hölting et al., 2019). While these conceptual and methodological ambiguities in the application of the multifunctionality concept may have potentially jeopardized its practical use in land management, recent works (Manning et al., 2018) have made substantial progress to disentangle the existing confusion in terminology.

Ecosystem multifunctionality has recently been “redefined” and two major strands of research have been characterized (Manning et al., 2018). The first strand of research quantifies multifunctionality based on ecosystem functions, typically at small spatial scales such as plots. It largely deals with the relationship between biodiversity and the number of ecosystem functions that are supplied within a particular land use type. Numerous studies have proven that high levels of biodiversity at multiple trophic levels are needed to sustain ecosystem multifunctionality (Soliveres et al., 2016). As different species provide different functions, this relationship depends on the functional diversity and redundancy in an ecosystem. Nevertheless, these studies generally underpin the important role of biodiversity for ecosystem functioning (Byrnes et al., 2014). Other studies belonging to this strand of research have analyzed the impacts of land use regimes on multifunctionality, as well as dependencies between forest structure and multifunctionality (Felipe-Lucia et al., 2018).

The second strand of research focuses mainly on larger spatial scales, often on landscapes being composed of different land use types. These studies define multifunctionality as the supply of multiple ecosystem services (including provisioning, regulating and cultural ecosystem services) across the landscape, and aim to evaluate the multifunctionality of a landscape by accounting for all ecosystem services used by people (Manning et al., 2018). Focusing on ecosystem services allows to shed a new light on the use of landscapes (Stürck and Verburg, 2017): instead of representing land use/land cover information, such studies aim to capture the complexity of social-ecological systems by making the difference between service provider units (i.e., potential ecosystem service supply) and beneficiaries (i.e., actual ecosystem service use). The foreground of this strand of research includes studies investigating the level of the use of these services, people's demand for ecosystem services, its distribution among different stakeholders (Mastrangelo et al., 2014; Plieninger et al., 2019) and different components of human well-being.

The two conceptual ways to define multifunctionality outlined here (ecosystem function-focused multifunctionality with a plot-based, ecological perspective vs. ecosystem service-focused multifunctionality with a landscape-scale, human-centered perspective) can help us understand the approaches used in existing studies regarding multifunctionality (Hölting et al., 2019). In the following sections, we reflect on the concept of multifunctionality from the latter, the landscape-scale, ecosystem service perspective.

The Capacity of a Landscape to Supply Multiple Functions and Services: Interactions at the Landscape Scale

This section describes the interrelations between human land use, biodiversity, ecosystem functions and services in multifunctional landscapes (Fig. 1) for biomes that are classified as “human biomes” or “anthromes” (Ellis and Ramankutty, 2008): (1) Humans shape landscapes through land use and management practices. (2) Landscapes contribute to a specific set of ecosystem functions, i.e. processes that maintain the internal functioning of the ecosystem, such as energy cycles or nutrient fluxes. Land use and management decisions also affect biodiversity, i.e., the diversity of genes, species and ecosystems, (3) either directly (e.g., through pest control or wildlife management) or (4) indirectly through changes in the landscape (e.g., through modification of forage opportunities or habitat quality). Biodiversity, on the other hand, also influences landscape structures (e.g., through grazing or creation of habitats). (5) Species and their functional traits influence and control ecological processes and functions (Byrnes et al., 2014). (6) Ecosystem functions eventually provide ecosystem services, in case they lead to the provision of specific goods and benefits to people, thereby (7) contributing to various components of human well-being (i.e., health, safety, material needs) (de Groot, 2006; MEA, 2005). (8) Finally, the production and consumption of ecosystem services is shaped by the location-specific demand for ecosystem services by people.

Since ecosystem functions and services interact, either enhancing or reducing each other, human land use and management decisions do never affect only single functions or services, but always multifunctionality as a whole. In addition to human activities, there are other important non-anthropogenic factors and drivers—such as climate, soils, landforms, biotic processes and natural

Fig. 1 Interactions between human land use, biodiversity, ecosystem functions and ecosystem services: (1) land use and management practices affecting landscapes, (2) contribution to ecosystem functions by landscapes, (3) direct effects on biodiversity, (4) interactions between biodiversity and landscape structures, (5) contribution to ecosystem functions by species, (6) supply of ecosystem services, (7) contribution to human well-being, (8) demand for ecosystem services. Icons designed by Freepik.

disturbances—that influence the potential capacity of a landscape to supply specific functions or services. However, it is humans who directly influence this capacity through land management practices and strategies that are often specifically tailored to promote or reduce certain functions or services. For example, pollination is promoted through beekeeping; soil erosion is reduced by targeted reforestation measures. Against this background, land use and management can be considered the most influential driver of landscape multifunctionality in human-dominated landscapes or “anthromes.” “Conventional biome systems” that do not take into account the impacts of human activities are considered less accurate than models that describe “human biomes” (Ellis and Ramankutty, 2008).

Multifunctional Landscapes—An Ecosystem Service Perspective

Why Adopting an Ecosystem Service Perspective on Multifunctionality?

First, translating ecosystem functions into ecosystem services is important to better understand land use interests and decisions

While studying ecosystem functions and their dynamics within landscapes is fundamental to understand the processes within ecosystems, the ecosystem service concept is embedded in a broad and inclusive framework that gives us the opportunity to translate this ecological complexity into a limited number of ecosystem services of interest for human well-being (de Groot, 2006; Turkelboom et al., 2018; see also Fig. 1). By assessing the value of ecosystem services that are most relevant to the people within a study area, we step from an exploratory lens on landscapes to a normative, anthropogenic perspective. This step is needed to better understand what people demand within a landscape, how they depend on certain ecosystem services and how they prioritize land use decisions for or against certain ecosystem services.

Second, including marketable and non-marketable goods can help steering management decisions toward increased sustainability

We typically manage landscapes for the supply of a few, mostly marketable goods and services such as food or timber (de Groot, 2006; Turkelboom et al., 2018). However, it is necessary to better understand the impacts of land use decisions for a wide range of ecosystem services. Besides these marketable goods, we demand and depend on ecosystem services that are non-marketable, such as many cultural and regulating services. Many of these non-marketable ecosystem services are heavily affected when landscapes are managed for the supply of one or a few ecosystem services only. On the other hand, non-marketable ecosystem services may be of key importance for steering management decision toward sustainability. For example, cultural ecosystem services, often closely related with the attachment of people to their landscape, can be crucial for long-term conservation: People who value their landscape are typically more willing to take stewardship for it and to invest in sustainable management (Fischer et al., 2017). While non-marketable ecosystem services are often intangible and therefore not included in conventional market-based analyses (de Groot, 2006), the ecosystem service framework provides methods to better account for the value of such goods and services (Turkelboom et al., 2018). Regulating services are often measured in biophysical terms, such as differences in air temperature, amounts of carbon stored in trees and soils, and nutrient content in soils. Cultural ecosystem services can also be assessed using direct measures (e.g., number of spots for recreation, educational visits, or artistic publications). In all cases, ecosystem services can be assessed using social valuation methods (e.g., structured surveys, participatory mapping and stated preferences) or econometric methods. The ecosystem service framework thereby helps quantifying multiple aspects of multifunctional land use, which eventually results in a more integral way of understanding land management.

Third, the ecosystem service concept can ease the communication of scientific findings to decision-makers

The ecosystem service concept has been designed to better communicate “wicked” (interlinked and complex) problems of environmental degradation, associated effects on social inequity and economic interests to a broad range of audiences, including decision-makers. It has been picked up by science-policy platforms ranging from local to global level, such as the UK National Ecosystem Assessment (UK NEA), the international TEEB initiative “The Economics of Ecosystems and Biodiversity,” or the Millennium Ecosystem Assessment called for by the United Nations in 2000. The ecosystem service concept further is an integral part of the Nature’s Contribution to People (NCP) concept recently developed by the Intergovernmental Platform for Biodiversity and Ecosystem Services (IPBES) and has been promoted as a tool to effectively illustrate trade-offs between different land use-decisions (Turkelboom et al., 2018). Different methods have been used to convey this information to policy makers, ranging from policy briefs and ecosystem service maps to public meetings with invited stakeholders, proposed action plans and guidelines. Moreover, the integration of long-term environmental costs (through payments for ecosystem services, PES) and the involvement of stakeholders in ecosystem service assessments can provide additional support to policy decisions that stimulate reflections upon landscape multifunctionality (de Groot, 2006).

Links to Sustainability and Resilience

The concept of landscape multifunctionality is strongly linked to the concepts of sustainability and resilience (O’Farrell and Anderson, 2010). Landscapes that offer a diverse and interlinked set of ecosystem functions generally have a higher capacity to withstand disturbances and to adapt to environmental changes (Byrnes et al., 2014; Foley et al., 2005). From an ecological point of view, such landscapes have long been considered as more resilient than those providing only a small number of ecosystem functions.

More recently, the resilience concept has been extended beyond its ecological meaning, in order to include human-nature interactions. Also from a socio-ecological perspective, a landscape supplying a more diverse set of goods and services has the potential to satisfy the demands of many different groups of people; hence, it can be considered more multifunctional. Such a landscape will also be more resilient to fluctuations in market prices of individual products and might eventually help mitigating conflicts that evolve from competing demands. Multifunctional landscapes are further associated with relational values, such as higher levels of place attachment, local knowledge and stewardship of the landscape by its inhabitants (Fischer et al., 2017). Thus, socio-ecological resilience relates to both the adaptive capacity of society to react to changes in the environment, as well as to the capacity of ecosystems to adapt to or withstand changes posed by humans (Mastrangelo et al., 2014).

Landscapes that are managed under the multifunctionality paradigm are further considered to be environmentally sound, socially equitable and economically feasible—the elements embedded in the sustainability concept. As resources are limited, land management needs to hold on to these three criteria in order to conserve natural resources, generate welfare and promote equity for current and future generations. Losing important ecosystem services in non-multifunctional systems can, on the other hand, have severe impacts for certain stakeholder groups and may lead to environmental degradation processes. The prevention of any kind of degradation processes through sustainable land management practices, on the other hand, has tremendous potential to reduce future costs of environmental restoration efforts (IPBES et al., 2018).

Toward Increased Multifunctionality of Landscapes

Remaining Challenges to Assess Landscape Multifunctionality

Selecting relevant ecosystem services and their indicators

Characterizing multifunctional landscapes via ecosystem service-based multifunctionality assessments remains challenging, as it is associated with a number of assumptions made in ecosystem service assessments and resulting uncertainties. The first crucial step is the identification and quantification of all relevant (i.e., representative) ecosystem services within the study area. The quantification and mapping of these services can be based on direct measurements (e.g., field observations and surveys), indirect measurements (e.g., remotely sensed proxies), look-up tables, models, or expert knowledge (Hölting et al., 2019). The increasingly inter- and transdisciplinary research on ecosystem services, together with the growing availability of ecological, social and remotely sensed data is promising to allow advances (Cord et al., 2017). However, limited temporal and spatial resolution of available data oftentimes poses constraints to landscape-scale ecosystem service assessments and produce uncertainties. To increase representability and legitimacy, the services and the indicators chosen to quantify each ecosystem service are best identified together with experts and relevant stakeholders of the study area (Mastrangelo et al., 2014; Turkelboom et al., 2018). The selected ecosystem services should further include all ecosystem service categories and be assessed following different approaches (i.e., ecological, economic and social), to minimize potential bias related to the valuation method (Martín-López et al., 2014).

Assessing the actual use of and demand for ecosystem services

Another major challenge is to assess the actual use of ecosystem services or the actual benefit that people obtain from nature. Studies predominantly assess the (potential) supply of ecosystem services, which is not directly linked to the actual use or the benefits derived from ecosystem services (O'Farrell and Anderson, 2010; Turkelboom et al., 2018). In the case of provisioning services, for example, a high supply can benefit the local population only if the product is consumed locally or the revenues remain in the area. In reality, however, this is most often not the case, as farms might be owned by external companies and the products are often exported to national or international markets. In the case of cultural services, on the other hand, a low service supply might be sufficiently contributing to people's well-being, if the level of supply meets their demand (e.g., opportunities for recreation). Assessing the demand for services or their actual use and benefits is therefore more useful to inform management and hence a currently fast developing field of research (Pleninger et al., 2019).

This is also closely linked to the challenge of obtaining a differentiated view on the beneficiaries of ecosystem services. Most studies do not differentiate between different groups of stakeholders and rather generalize that the supply of ecosystem services is contributing to the quality of life and human well-being in general. Especially in multifunctionality assessments, hotspots of ecosystem service supplies are often equated with hotspots of increased human well-being (Stürck and Verburg, 2017). This bears two main risks: (i) first, the risk that management recommendations are based on such hotspot analyses instead of the location-specific supplies and demands for ecosystem services and (ii) second, the risk of overlooking the demands of vulnerable stakeholders placed outside the assessment and decision-making processes. Research advances should therefore not only differentiate between demand, supply and actual use of ecosystem services, but also between different groups of stakeholders.

Assessing multifunctionality at the right scale

The capacity of a landscape to supply ecosystem services, as well as the demand of people for certain ecosystem services vary within and across landscapes: while a small patch can in most cases only produce one or a limited number of ecosystem services (e.g., field scale), a larger amount of different ecosystem services are being produced within a larger scale (e.g., landscape scale). Similar to the land sharing/sparing debate (Ekroos et al., 2016), it is important to consider where and at which scale (extent) increasing multifunctionality is needed. It is for example debatable, whether multifunctionality needs to be implemented at the plot scale, or whether patches with lower multifunctionality are acceptable, providing that management strategies promote a high level of

multifunctionality at the landscape scale (Felipe-Lucia et al., 2018). In order to orient multifunctionality assessments toward the development of specific management strategies, it is important to assess multifunctionality at the spatial scales relevant for implementation (Turkelboom et al., 2018). In practice, the choice of spatial scale for ecosystem service assessments, however, often depends on the availability of data, the resolution of underlying field or modeled data, or on administrative scales relevant for their management (Stürck and Verburg, 2017).

Despite the remaining challenges to assess multifunctionality, such analyses can provide highly valuable, area- and context-specific information for policy-makers. In particular, the identification of priority ecosystem services for assessment and of relevant stakeholders needs to be a transparent and recurrent process that will vary depending on the study area.

Governance Across Sectors and Scales

Landscape management is influenced by a network of administrative bodies, institutional arrangements, individuals and stakeholder groups on different scales of governance (MEA, 2005; Nagendra and Ostrom, 2012). A transition toward multifunctional landscapes therefore requires deep system changes. First of all, multifunctionality needs to be the common goal across socio-economic sectors and administrative levels. Stakeholders of different sectors should formulate joint objectives to increase multifunctionality and work collaboratively to reach their goals (O'Farrell and Anderson, 2010). Relevant stakeholders include governmental bodies (e.g., provincial and municipal administration), "influential" land users (e.g., companies, land owners, farmers, foresters) and "non-influential" land users (e.g., recreationists, citizens) (Turkelboom et al., 2018). Cross-sectoral work, however, is a major challenge in countries which are predominantly sectorally organized.

Besides the different sectors, there are different scales of governance that influence land use and landscape management, from the international agreements to their implementation at the local level. In practice, countries follow these international agreements, but apply their policy instruments at the national level. In turn, countries dictate decisions on regional or provincial levels and design regional management plans to support municipalities and rural communities. In many cases, management practices locally framed and implemented will potentially have the strongest impact on ecosystems and the services they supply. While multifunctionality is often defined as a management aim at the landscape level, policies on multifunctionality have to be formulated at all scales of the decision-making process (Nagendra and Ostrom, 2012) to achieve a coherent strategy.

Implementing a Strategy for Multifunctional Landscapes

Increasing the multifunctionality of landscapes typically requires multiple changes in landscape management that are often not straightforward. For example, diversifying local agricultural production requires changes in market structures, commercialization channels, education, financial and policy instruments. While such systemic changes need time, other smaller-scale and practical viable solutions toward increased multifunctionality can be achieved in the meantime. We argue that a step-by-step adaption of current management systems is most promising to increase the multifunctionality of landscapes. It goes without saying that, for example, the introduction of landscape elements that increase landscape heterogeneity (e.g., ponds, hedgerows, trees, flower strips) and offer key habitats, forage and nesting opportunities (Foley et al., 2005; Mastrangelo et al., 2014) can substantially increase multifunctionality. Such elements further affect multiple ecosystem functions (e.g., nutrient cycles, photosynthesis or evapotranspiration) and eventually increase multiple ecosystem services (e.g., aesthetic value, buffer capacities or climate regulation) (de Groot, 2006) (Fig. 1). Other management practices that can be adapted to foster multiple ecosystem services in human-dominated landscapes include a reduction in the use of pesticides and fertilizers, which should be extremely precise and species-specific, a focus on diversity and self-sufficiency instead of crop yield, and sustainable soil and water management practices. On the other hand, changes in the social system toward a polycentric governance can contribute to adapting global and national policies to local needs while engaging a more diversified set of stakeholders in the decision-making processes of landscape management (Nagendra and Ostrom, 2012). In general, it is crucial to look at the landscape in a more integral way in order to increase multifunctionality and to achieve a more equal distribution of their services. Still, we need a better understanding of the interrelations between management practices and their effects on ecosystem functions and services at the landscape scale. In turn, how such landscape management policies affect different sectors of society is crucial to promote sustainable livelihoods and to reduce social and environmental conflicts. Context-specific solutions are required to design multifunctional landscapes. Therefore, it is also crucial to integrate local knowledge holders in decision-making processes.

Conclusions

While we are facing a number of environmental crises, a more integral way of land management is required to achieve multifunctionality at the landscape scale. Global population growth and changing consumption patterns have led to a growing demand for food, land, water and energy. At the same time, intensive land use affects water quantity and quality, soil fertility and air quality in many parts of the world. On top of that and exacerbated by climate change, the loss of biodiversity is predicted to increase, which will have unpredictable consequences for ecosystem functioning and ecosystem service supply at the landscape scale. In essence, land is a limited resource that is subject to a lot of pressures. The multifunctional use of landscapes has been advocated as a way to manage land in a sustainable way that maintains ecosystem functioning and conserves natural resources for future generations.

It means promoting multiple ecosystem services instead of focusing on the supply of a few. Spatial planning must therefore aim to change human-dominated landscapes into more multifunctional systems. The design of such multifunctional landscapes is always area- and context-specific, as different sets of functions and services can be provided and are required in different landscapes. Additionally, the demand for ecosystem services depends on local stakeholders, who need to be involved in regional management plans. While it is challenging to find “optimal” multifunctional landscape solutions, there are already a few promising examples (e.g., increase of green space in urban areas, employment of agroforestry and sustainable intensification practices, and financial support systems to increase landscape structure and biodiversity; Foley et al., 2005).

Abstract

Low-intense agroecosystems may be key for mitigation of vulnerability to climate change, as to build ecological and social resilience of local communities.

As an example of low-intensity systems, the article will focus on olive land use dynamics occurring at different temporal and spatial scales in the island of Sicily. Sicilian olive intercropping systems have resulted in the formation of heterogeneous cultural landscapes and heritage that supports place-based and practice-based know-how, drawing on transmitted and new knowledge—what we call Biocultural Heritage. The domestication and continuous careful management of these trees by locals have been a crucial element for their longevity: they can thus be seen as stabilities in a changing landscape along time and space.

The article crosscuts history and spatiality at different scales to allow the olive trees of Sicily to “talk” about their millennial entanglements with the other elements of local ecosystems, man included. Considered biocultural refugia able to preserve both agricultural biodiversity and traditional ecological knowledge, their social and ecological history is explored through the identification of breaking points in time and spatial nodes of connection.

Such enduring landscapes are increasingly under threat due to climate change and intense land abandonment; their progressive fragmentation represents a huge threat for their ecological complexity, agricultural practices, biocultural heritage and socio-economic conditions of local communities. We conclude the article advancing suggestions for their future stewardship.

Introduction

Accelerating climate change, as rapid socioecological modifications of land use, calls for new deeper transdisciplinary knowledge on agro-ecosystems. Land use has influenced many aspects of the environment and is also interlinked with regional and global climate. Quantifying land use changes and their effects on past and present environment is a challenge; nonetheless, such knowledge is needed if we want to develop land management strategies for climate warming mitigation. The recognition of the ecological function of agricultural societies is fundamental to inform and inspire sustainability research (Bird and Nimmo, 2018) and low-intensity farming areas are excellent study cases to investigate and find evidence for landscape effects on ecological and farming systems. Ancient olive groves, agro-sylvo-pastoral systems, traditional vineyards agro-economic systems are a few examples, today recognized as Globally Important Agricultural Heritage Systems since they play a crucial role for agrobiodiversity conservation and livelihood (FAO, 2018). In rural landscapes, “natural” ecosystems have a long history of coexistence with agricultural land use systems as evidenced by the spatial extent of cropland, rangeland, and village anthromes overtime (Ellis et al., 2010). The functionality of these landscapes depends on the interactions among natural ecosystems, agroecosystems, and the social and cultural characteristics of the people that create and manage them (López-Pintor et al., 2018); low-intense agrosystems may be key for mitigation of vulnerability and to build ecological and social resilience (Schermer et al., 2018).

The Mediterranean environment, and its dynamics over time, particularly in relation to agriculture, have been the topic of an animated debate. There is a Mediterranean “problem” to solve: does the Mediterranean represent an environment which has

been able to support agricultural way of life (based, among other crops, on olive and mixed agricultural cultivation) for more than eight millennia and can this continuity be thus defined as “sustainable”? Or has the Mediterranean been the place of environmental and devastation due to climatic anomalies, mismanagement, exploitation of natural resources and destruction of primeval forests? These questions represent different ways of viewing Mediterranean agricultural and semi-natural anthromes (Emanuelsson, 2009).

Regardless, we witness today the alarming disappearance of both farmed areas and connected local agro-ecological knowledge. The few land users remaining face a quite pressing dilemma: agricultural practices are considered to be responsible for habitats fragmentation and destruction (Campbell et al., 2017) while, on the other hand, decline in traditional low-intense farming has often had negative effects on biodiversity and high species richness at local scale (Beilin et al., 2014). Simplistic generalizations have led to low-intense agrosystems being seen as almost immune to climate change, soil degradation, loss of biodiversity, and reduction of resilience (see critical discussion in Iuga et al., 2017). Knowledge co-created with local communities have shown instead how these areas are not only affected by such problems but, even worse, they suffer from serious economic and social marginalization, as land degradation (Biasi et al., 2017; López-Pintor et al., 2018).

Among low-intensity agroecosystems, our contribution focuses on Mediterranean intercropping systems, with special attention to land use dynamics in olive cultivation occurring at different temporal and spatial scales in the island of Sicily. Mediterranean islands are characterized by the high level of diversity in biotic and environmental conditions. Their complex historical biogeography makes them important ecological reservoirs, informing us about the long-term entanglements between human and environment and their crucial role in the preservation of such biocultural heritage (Médail, 2017). Landscape persistence should be given the same attention as landscape change (Lieskovský and Bürgi, 2018) and this is the starting point of our analytical approach: here we use vegetation stability and its different spatial patterns displayed in the landscape as indicators of diverse land uses, management strategies and adaptive dynamics. Olive land use systems are of extreme longevity as olive trees can be even several thousand years old. Their peculiar manifold spatial configurations, shaped by the millenary interplay between humans and nature, provide a unique opportunity to study long-term adaptability processes, map land use relative temporalities and understand the logics behind them. Using olive trees as both spatial control points and as historical “archives”, we will here embark on a journey through the spatiotemporal land use variations in Sicily, while exploring historical trajectories, the formation of culture and socio-ecological adaptation. After a brief geographical background, the article will delve into the biogeography of Sicilian woody vegetation, looking at olive patch matrix interactions within a millennial perspective through the analysis of breaking points in time and spatial nodes of connections. Reclaiming the endurance of olive biocultural heritage in Sicily, we conclude the article providing suggestions for its future stewardship.

Geographical Background

Mediterranean islands, with a wide range of sizes, altitude and remoteness, are reservoirs of unique genetic lineages, mainly for most endemic plants, in other words “current refugia” which ensure the conservation of plant biodiversity. They are also key entities to disentangle the role of environmental versus human pressures in the long-term preservation of these biodiversity hotspots and their cultural heritage (Médail, 2017) (Fig. 1).

The island of Sicily itself has an overall surface of c. 25,703 km² and includes also five smaller archipelagos. Geomorphological features have been crucial for the development of its flora and fauna, since most of the surface is made of hills (62%) and mountains (24%) overlooked by Mount Etna, the highest active volcano in Europe. The entire island is quite geologically heterogeneous, also for micro-climates, vegetation and land use. Sicily has approximately 2700 vascular-plant species, 11% endemic and a wide diversity of cultivated species, with most of the territory covered by “cultivated lands and temporary fallow lands” (846,470 ha), “olive groves and other dry crops” (336,528 ha), “citrus groves and irrigated orchards” (158,592 ha), “vineyards” (142,558 ha), “greenhouses” (15,608 ha) and “hazel groves” (12,411 ha). The natural wood communities occupy about the 6.78% of the total island, limited to relatively small biotopes living in protected areas. Other widespread features are Mediterranean grassland (12.84%), used for grazing and regularly affected by wildfires, and azonal vegetation as shrubs, maquis and garrigues in rocky cliffs, lava fields, riverbeds, sandy coastal stations and brackish marshes (Benedetto and Giordano, 2008; Gianguzzi et al., 2015). Urbanized areas represent only the 4.86% of the regional surface; the overall population is around 5 million (ISTAT, 2019).

Talking With the Trees

Ecosystems and their specific set of land use practices are a result of repeated feedback between land use as an ecological process and the response of the ecosystem itself: they co-evolve, producing in complex adaptive systems characterized by multiple timelines with different rates of change and persistence (Sinclair et al., 2017). To understand such living dynamic systems we can interpret their relationships with the environment, while recognizing them as fully agents in the spatial and temporal evolving dynamics of the landscape; what we here refer to as “talking with the trees”. Thus, here we will explore the ecological and social history of olive trees by crosscutting time and space at different scales. Through the identification of historical breaking points (significant events in time which could have affected olive trees dynamics in the island) and spatial nodes of connections (olive trees patterns at various spatial scales) occurring over the long term in Sicily, we reveal how such hybrid and heterogeneous temporal entanglements have a spatial dimension displayed in the landscape. The result is a holistic approach to complexity which merges many kinds of evidence

Fig. 1 Location of sicily in the Mediterranean sea and Europe (Ferrara, 2016 on dataset provided by ESRI).

to reach new understandings about human- environment relationships over long-term historical transformation dynamics and multiple spatial scales.

Biogeography of Woody Vegetation in Sicily

With a rich biodiversity and long history of human-environmental interactions, the Mediterranean region is characterized by a high degree of spatiotemporal heterogeneity in vegetation patterns. Published syntheses of multiple modern and fossil pollen records have revealed subclimax vegetation communities, the long-standing evidence of vegetation turnover and the complex interactions between plant assemblages, disturbance and climate, as the evergreen shrub dominated by Oleaceae (Sadori et al., 2016; Woodbridge et al., 2018). Peculiar to the central Mediterranean is the ability of vegetation to rapidly respond to climate change, being developed in a complex physiographic system that enhances high diversity and assemblages, often located in ecological niches close to each other, coexisted throughout the glacial–interglacial cycles of the Quaternary, ready to alternately develop following climate oscillations. The vegetation history of the central Mediterranean is further characterized by a long-lasting and intense human impact on the landscape through agropastoral and silvicultural practices, forest clearance, fires, and demographic increase (Di Rita and Magri, 2019).

Woody Mediterranean vegetation has been dramatically influenced by human activities for thousands of years. Since the Neolithic, human influence on ecosystems, especially on forests, have been intense and the profound transformations of natural into cultural landscapes are the result of millennia of human activities. With the exploitation of resources provided by tree species, humans interfered with their natural distribution, gathering or cultivating some of them (e.g. olive, walnut and chestnut trees) since ancient times. Olive (*Olea europaea* L.) was one of the most important fruit trees in the ancient Mediterranean region and a founder species of horticulture in the Mediterranean Basin, considered the most prominent and economically important fruit tree, providing edible fruits and, more importantly, storable oil used since antiquity for cooking, lighting, cultic and medical purposes. In the wild, olive (*Olea europaea* L. subsp. *europaea* var. *sylvestris*) grows in habitats characterized by a typical Mediterranean climate, usually hilly areas as part of the garrigue and maquis. Whereas the wild olive is considered a sensitive bioindicator for the Mediterranean bioclimatic zone, cultivation has caused the species (*Olea europaea* subsp. *europaea* var. *sativa*) to surpass its natural bioclimatic limits and to be grown at higher altitudes and latitudes as well as in areas more arid than its wild habitats (Langgut et al., 2019). Today, the olive tree is also appreciated for its multi-functionality: hydrogeological safeguarding of mountains and hills, climate mitigation actions, landscape enhancement (Brunori et al., 2017).

Patch Matrix Interactions Within a Millennia Perspective

Rural landscapes reveal a complex system of human-environment interactions across extended temporal trajectories. Vertically, through time stratifications there is a diachronic accumulation of changes occurring through dynamic interactions between human interventions and climatic, geomorphological and ecological changes. Horizontally, we have the formation of heterogeneous mosaics of spaces created by both temporal dynamics (historical stratification as explained above) and a series of heterarchical relationship between climatic conditions, landforms, soils, vegetation and human activities (Bazan et al., 2019). Ecosystems, and their specific set of land use practices, are the result of repeated feedbacks between land use as an ecological process and the response of the ecosystem itself: they co-evolve, producing biocultural diversity, in complex adaptive systems characterized by multiple time-lines with different rates of change and persistence (Crumley et al., 2017).

Sicily is considered a special historical-naturalistic laboratory: shaping vegetation through land use over millennia, humans have been the geodesigners of the Sicilian landscape. Olive trees, living in the same place for centuries, are keystone biocultural elements that preserve both biodiversity (Prevedello et al., 2018) and related traditional agro-ecological practices (Calvet-Mir et al., 2018). They are an extremely unique case of persistence; as a perennial crop, they represent long-term investment, still producing for both self-consumption and trade markets. Even if abandoned, trees always remain on the field and survive, being able to adapt to specific climatic, topographical and soil characters, while exhibiting high plasticity (particularly for the native varieties) and optimizing the genotype-environment relationship (Marchi et al., 2018).

As a result of the interaction between natural and anthropogenic factors, distinct patterns of olive groves can be found in the rural landscape of Sicily today: scattered old- century olive trees, ancient olive orchards, mixed crops, olive trees in terraces and pocket terraces, olives as boundary markers, small- scale geometric plantations as exemplified above (Ferrara, 2016). In other words, olive different patterns in spatiality represent different biocultural timescapes since each of them is expression of specific cultivation modalities related to cultural negotiations with nature (Huebener, 2018) occurred at different temporalities in Sicilian history (Figs. 2 and 3).

The different spatial patterns of olive trees can be considered as different ecogeographic units, defined by the physical environment, the multiple land uses, management strategies and production practices. Their spatial configuration has a great importance for landscape function: the gain or loss of a land-use has different consequences depending on where it takes place because it can affect biodiversity, modifying individual patch size and connectivity with similar patches, acting as ecological barriers or corridors for species dispersal, thus potentially increasing or decreasing biological diversity.

Fig. 2 Patch matrix interactions between different olive historical and spatial patterns in the same landscape, example 1.

Fig. 3 Patch matrix interactions between different olive historical and spatial patterns in the same landscape, example 2.

Breaking Points in Time

Sicily was part of the natural distribution area of *Olea europaea* pollen rain during the Pleistocene and served as areas of refugia during the Last Glacial Maximum (Langgut et al., 2019). Sicily, being an island, played a large role as a shelter of a significant number of endemic trees (Médail et al., 2019): evidence of *Olea europaea* var. *sylvestris* during the Preboreal have been found in several paleosites of the island, suggesting an early colonization of the species and its adaptation to local ecological conditions (Sadori et al., 2016). Reconstructions of the Holocene vegetational dynamics and regional fire history in the evergreen vegetation belt of coastal areas of Sicily has shown that there was a fire-prone open grassland until ca. 8050 BC, when an increase in *Olea* percentages is registered; such rapid afforestation was climatically induced (due to higher moisture levels) and affected the intensive early Neolithic agriculture, in the sense that the rise could have reduced the harvest success and thus forced people to migrate in search of new agricultural land, from the coast to the hilly country of central Sicily. Vegetational conditions remained almost stable for several millennia, suggesting that the landscape was still open, probably comparable to the present-day *Olea*–*Pistacia* maquis, even during periods with highest *Olea* occurrences. The fire frequency remained rather low until ca. 800 BC, as frequent anthropogenic burning began, causing a collapse of the coastal forest (Langgut et al., 2019; Sadori et al., 2016).

Dating the beginning of olive cultivation in Sicily remains quite difficult. Being *Olea* dominant in the local natural forest (so its pollen values significantly high in humid phases), such marker cannot be a clear temporal indicator of the date for domesticated olive cultivation. Some chemical signatures of olive oil have been instead identified in three Early Bronze pottery vessels from southern Sicily, dated to the 5th and the beginning of the 4th millennium BP (Tanasi et al., 2018); we could then infer olive cultivation and oil production from that period onwards. The cultivation of olive trees was in any case a process mediated by sociocultural adaptation; probably the first domestication started very experimentally, originating as part of more mixed cultivations with the purpose to increase fruit size and improve their quality, as well as to produce oil (Forbes and Foxhall, 1978).

With the domestication of the oleaster started a new era in land use, the tree crops or “wooden crops” (Emanuelsson, 2009) system, which has persisted in several forms until today. Near-East human migrations to the West Mediterranean Basin brought new olive cultivation methods into the island. After the Roman conquest of Sicily in the 3rd century, the impact on the environment increased and Romans implanted an extensive agrarian system (the *latifundum*) based on wheat and vineyards, accompanied by the presence of scattered olives. During the final centuries of the Roman period (4th–6th centuries) the agrarian economy in Sicily reached its peak, favored by a period of increased humidity which made it easier to expand cultivation. Such fortunate climatic conditions allowed the late Roman-Byzantine society to continue into the early Medieval Period without major interruptions.

Sicily's early-Medieval era of prosperity seems to have come to an end around AD 750, when a sudden climatic shift toward aridity caused a change in the local hydrological conditions crucial to agriculture. Agriculture had to deal with a changed climate (the beginning of the dry period is dated AD 750–850), as well as a general socio-economic decline, could have weakened the Byzantine communities in Sicily, making them vulnerable to Islamic invaders, who completed their conquest of the island between AD 827 and 878 (Sadori et al., 2016). With the arrival of the Arabs on the island, an authentic agrarian revolution began: introduction of new crops, innovative soil improvement techniques and hydraulic systems which contributed to a better use of water resources, a temporal and spatial differentiation of production and a more integrated view of the agricultural system in all its components (irrigation, energy, micro-climate and aesthetic functions): a completely different approach to agriculture which, for its holistic nature, could be indeed defined as agroecology. Such structural revolution marked deeply the Sicilian agrarian landscape; it was the beginning of the *coltura promiscua* system, based on an authentic intercropping of the fruit trees (olive included) (Barbera and Cullotta, 2016).

During Late Middle Ages the first forms of feudal system were introduced in Sicily, even though based on the old structure of the Roman *latifundia*. Olive trees were not yet considered systematically as a crop by themselves, but just an integration to the main cereal production of extremely large estates owned by noble families, or by bishops, and managed locally by tenants. Late Medieval was also the period when several oil-mills started to be hidden and thus realized underground, testifying late Medieval fears of the Turkish pirates' incursions in the island (von Falkenhausen, 2013; Tyerman, 2005).

In the 17th–19th centuries, together with the rest of Europe, Sicily was affected by the Little Ice Age. Several clusters of climatic extreme events occurred around 1691–1694, 1713–1714 and 1812–1814, which affected the island olive crops remarkably, due to heavy snowfalls and frosts. A frost of -13°C kills the olive to the ground; its base survives, but it needs to be re-grafted and takes several years to produce olives again. Ancient olives still alive today, as multi-stemmed trees, contain quite interesting records of historic frost damages (Grove and Rackham, 2001).

Deforestation and early agriculture mechanization started in Sicily in the 20th century, following the overall European trend of intensification and standardization. Immediately after World War I, the Fascist regime revived the old Roman concept of Sicily as the “granary of Italy”, but the cultivation of cereals on a large scale was not well managed and impoverished the soils (Martini et al., 2016). The *latifundia* system was officially dismantled after World War II, but the new land system (based on small-scale private properties) was not able to provide peasants with enough means; moreover, even though legally dismantled, the effects of that land structure are still dominant in Sicily today through the influence of rural forms of mafia (Lupo, 1993); olive cultivation has become a mean of resistance for small-scale land users, within a system devoted mainly to cereal cultivation and husbandry.

In the last 50 years, the implementation of measures under the European Union Common Agricultural Policy (CAP) has brought an increase in crop productivity through the massive use of mechanization and pesticides: intensive olive plantations have appeared in coastal areas and inland hills, while the most rural and inaccessible locations have been characterized by a high degree of abandonment. From the 1970s, the old *coltura promiscua* of the island (together with its biodiversity and agroecological measures to contrast soil erosion and habitats degradation), started to disappear, while new modern terracing and hydraulic systems, stone-clearing and stone-made artifacts have become the protagonists of the agricultural landscape transformation (Barbera and Cullotta, 2016).

Nowadays, despite their huge ecological and cultural importance, olive trees (both old-century trees and younger ones) covers a total surface which is no more than 6.23% of the island (our elaboration on data from ISTAT, 2016). A number of EU programmes have been tackling rural abandonment since 1994, trying to ensure the survival of the olive intercropping systems, but so far they have had little effect (Ferrara, 2016).

Spatial Nodes of Connection

Space is intertwined with time in simultaneities ongoing of histories and geographies (Massey, 2006). In this sense the landscape has always the nature of “work in progress” (Ingold, 1993, p. 162), in which we can read spatiality and temporality.

Focusing on the occurrence of the olive trees as a single plant species and on the typology of their spatial connectivity, we will here discuss the high level of heterogeneity in their spatial and temporal patterns.

Terraces

There are several old and hand- built terraces in the mountains and hilly areas of Sicily (Figs. 4 and 5).

The terraces system has permitted cultivation on slopes with an inclination of even up to 75% (Blondel, 2006) and they have always been a way to fight soil erosion. Built with stone walls, they run horizontally across slopes, while pocket terraces surround individual trees on very steep slopes, where it was impossible to realize proper terraces (Foxhall, 2013). Unfortunately, there are no detailed data and information about all the terraced areas in Sicily since, due to their marginal position, they have always been the first places to be abandoned. Terraces are also very difficult to date, but from the ancient trees standing on them we could infer their age. Today many of them are affected by soil erosion and degradation, thus in many cases they are hidden by overgrown vegetation (La Mantia et al., 2011). Olive trees have always been a traditional crop suitable for terraced areas, and in fact many ancient trees could be found on them.

The agroecological value of terraces is huge. As a land management system, they are not only able to produce value from steep slopes, transforming them into productive areas; they also protect or slow down potential erosion and sloping processes, improving the moisture level and consequently the micro- climate. Terraces are often located between woody areas and open field crops, so they also prevent fires from propagating. Finally, their role in biodiversity conservation is crucial since in a terraced system it is possible to find a wide group of different habitats and ecosystems (Barbera and Cullotta, 2016).

Coltura promiscua

Coltura promiscua (tree species intercropping, in combination with pasture or grain cultivation), is one of the most ancient land use patterns in Sicily (Fig. 6).

Originally, the aim of mixed agriculture was the minimization of crops loss; on the island, *coltura promiscua* landscapes are located mainly in complex and transitional geomorphological contexts as between hills and high mountains. Mixed cropping, often close to urban settlements and agro-forestry systems, creates closed landscapes characterized by traditional and highly patch-intensive cultivation mosaics, with the olive tree as a significantly constituent. In addition to its economic importance and peculiar historical identity, the olive tree in a *coltura promiscua* setting plays a very important role in preventing soil erosion. This is particularly significant in more marginal and degraded areas, that are often semi-abandoned nowadays. The fuzziness of the boundaries in a *coltura promiscua* system makes it difficult, in some cases, to locate different crops, or to differentiate between pastures, Mediterranean scrubs, or cultivated and native trees, as the gradient of combinations may vary (Barbera and Cullotta, 2016).

Olea europaea woods remains and trees outside forest

In the island there are some remains of ancient *Olea europaea* woods, including the Mimiani olive wood and some abandoned woods in the Hyblaean Plateau; *olea* semi-woods today could be also the signs of ancient abandoned orchards (Ruhl et al., 2011).

Scattered olive trees, or trees outside forest, are quite often present in the Mediterranean cereal open fields interplanted with typical Mediterranean woody crops such as olive, grapevine, almond and carob. In the inner areas of the island this spatial pattern could be often found, since such open fields are in many cases what remains of more and less ancient *latifundia*. It is also possible to find lines of old-century olive trees planted as boarder markers and protection against wind for citrus groves.

The multifunctional role of the trees outside forests in the Mediterranean agricultural landscapes is huge, since they play the key role of ecological corridors in those areas characterized by intense and mono-culture land use (Marchetti et al., 2002).

Fig. 4 Remains of ancient terrace systems.

Fig. 5 Pocket terrace covered by overgrown vegetation.

Fig. 6 Example of coltura promiscua (intercropping system) with olive and several other tree species.

Contemporary olive groves

Contemporary olive groves are characterized by a typical straight geometric structure. They may be found in hilly and plain areas of the island and their extension usually does not exceed the 3–4 ha, unless in the case of highly intensive plantations. Trees in such groves are usually very young (from 1 to 60 years old approximately). This type of spatial pattern emerged as a result of the 20th century agriculture intensification, even though some types of specialized olive groves could also be found in ancient large estates. Nonetheless, strictly geometric olive groves are mostly the result of the CAP implementation in Sicily, since several subsidies have been granted to farmers in order to allow them to plant new orchards according to spatial rationalization logics over the short-term (Ferrara, 2016).

The Endurance of Olive Biocultural Heritage in Sicily

Worldwide, many of the most biodiverse landscapes have been produced by long-term, anthropogenic management practices. In places where local management has been discontinued, or cultural landscapes have become relict, historical-ecological research has

demonstrated that the absence of humans can lead to a decline in species diversity, landscape heterogeneity, and threats to livelihood, also in relationship to the cultural significance of the social practices embedded in the landscapes they produce. Local ecological knowledge, traditions, social norms, and languages are intimately linked with the landscape, and crucial for both biological and agro-ecological diversity.

In Mediterranean agro-ecosystems, old-century olive trees are a unique example of the long-term stewardship relationship between people and nature (Allen et al., 2018; Chan et al., 2016). The domestication and continuous careful management of olive trees by locals have been crucial for their longevity; they can thus be seen as stabilities in a changing landscape along time and space and as living biocultural refugia (Barthel et al., 2013), preserving biodiversity and the extraordinary “melting pot” of traditional local agro-practices and different ecological knowledges that have crossed the island of Sicily for millennia.

Local land use practices and traditional agro-ecological knowledge has brought a high endurance and adaptability of these social- ecological systems, which are linked both with biodiversity, rural identity and heritage (cf. Lindholm and Ekblom, 2019). We consider Sicilian ancient olive trees as continuities in the historical landscape. Their quite unique longevity and resilience, together with their special spatial configurations, offer the unprecedented opportunity to study long-term adaptability processes, mapping land use relative temporalities and understanding the logics behind them.

Conclusion: From Carving up to Transformative Stewardship

In complex Mediterranean agro-ecosystems is imperative to counteract soil and land degradation, water depletion, rural area depopulation, as well as the loss of local ecological knowledge. A better understanding of the multiple use and functions of tree crop landscapes will contribute to improve food security, land quality and conservation of natural resources.

Biocultural Heritage is a new and enabling concept in terms of supporting local advocacy groups, legal frameworks and agricultural innovation by and for local communities. Importantly, practices related to Biocultural Heritage are closely linked to the construction and confirmation of identities and social cohesion that are place-based and drawing on heritage (Lindholm and Ekblom, 2019).

A long-term ecological model on how traditional systems evolved to cope with vulnerability is needed to build resilient communities. Through the identification of landscape transformations, insights may be gained into important issues such as their responses to anthropogenic and environmental pressure, enabling researchers to predict the impact of future global changes. These enduring landscapes are in fact increasingly under threat due to climate change and intense land abandonment; their progressive fragmentation represents a huge threat for the ecological complexity of rural landscapes, their agricultural practices, cultural heritage, and socio-economic conditions of local communities (Biasi et al., 2017).

Tracing Sicilian olive land use across different spatial and time scales may consequently allow for an exploration in the local engagement processes with vulnerability and the related socio-ecological adaptation strategies. Land use play a crucial role because on one hand it is affected by climate change but, on the other hand, it has the potential to mitigate climate change (Schermer et al., 2018). Paradoxically low-intense agroecosystems could play today a strategic role in tackling the effects of climate change, while maintaining ecological diversity, improving adaptability and putting into practice a sustainable model of land use which may go beyond business-as-usual logics. The historical role of agriculture in creating semi-natural anthromes (Ellis et al., 2010) is still not fully appreciated by many; nor is the fact that for many European high nature value areas the only practicable, socially acceptable and sustainable management involves the continuation of low-intensity farming. Ecologists and conservationists should think less of “remnants of habitat being left amongst farmland” (Signal and McCracken, 1996, p. 413) and more of farmland anthromes for which optimum management practices need to be co-developed with local communities; while, at the same time, emphasis on site-based conservation should be complemented by strategic initiatives promoting a broader management approach at the landscape scale. Within a transformative perspective pursuing a new meaningful re-coupling between ecosystems and social systems, land use and local conditions should be understood in their dynamic relationship, in which agrosystems resilience must be always considered in a critical perspective, and where the simplistic reintroduction or maintenance of traditional farming could not be the panacea because these systems may be poorly equipped to cope with new environmental conditions. If agroecosystems, included the traditional ones, are a constantly changing heterogeneous patchwork of relations between people, plants, animals, other organisms and the environment happening at different temporal and spatial scales, how can this dynamism and these relations be maintained?

The problem is general, but the solutions cannot be generalized, because they need to be tailored to different local contexts and co-developed with locals, within an overall framework that consider farmlands as biotopes having ecological value by themselves. It is within this framework that transformative stewardship promotes different ways of understanding the environment and human-nature relationships, based on the knowledge of ecological and social interdependencies organized in networks of interactions reconnecting people to the biosphere, changing human behaviors at the individual level but also promoting collective actions, emphasizing relationships between people about nature, including their emotional and cultural dimensions.

Such type of stewardship emphasizes the diversity of values and responsibilities but also the need for fundamental social change in order to ensure that conservation efforts would not exacerbate social, democratic and ecological vulnerabilities. Based on adaptive co-management, transformative stewardship considers that we can increase the resilience of a system by using science and social learning, building dialogues based on a form of ecological solidarity that allows for a plurality of perspectives.

Abstract

Protected areas cover about 15% of the Earth's terrestrial land, and there are current efforts in place (e.g., Aichi Target 11) to increase the extent of protected areas globally. Although some protected areas have shown to slow the loss of natural habitats and biodiversity loss, there is great variability in the extent to which protected areas are directly impacted by humans. Anthropogenic biomes, or anthromes, can vary within and across protected areas, as some protected areas have little human impact while other protected areas have intense human impact. However, these anthromes have changed over time within and outside of the protected areas. Given the calls to increase the extent of protected areas globally, it is important to take anthromes into consideration as a factor in determining where protected areas will best serve biodiversity conservation.

Protected Areas

Globally, ~15% of terrestrial land and 4% of marine areas are protected in more than 240,000 protected areas (Fig. 1: Protected areas). The United Nations Environment World Conservation Monitoring Centre (UNEP-WCMC) has quantified the extent of protected areas in all countries and territories that are classified as UN Environment Regions. As of July 2019, the percentage of

^aUNEP-WCMC (2019). Protected Area Profile from the World Database of Protected Areas, July 2019. Available at: www.protectedplanet.net.

^bPercentages do not always add to 100 due to rounding.

^cOther consists of three categories: not reported, not assigned, and not applicable.

terrestrial area that is protected varies by geographical region, ranging from 7% and 9% in West Asia and North America, respectively, to 86% in the polar region (Table 1). For marine areas, these values range from 4% and 5% protected in Africa and West Asia, respectively, to 34% protected in the polar region.

The International Union for Conservation of Nature (IUCN) has defined main categories for protected areas, and these categories define the objectives of the reserves in the category, have distinguishing features based on the level of human activities, and have specific roles in the landscape or seascape. The IUCN categories are: Ia (strict nature reserve), Ib (wilderness area), II (national park), III (natural monument or feature), IV (habitat/species management area), V (protected landscape/seascape), and VI (protected area with sustainable use of natural resources). Some protected areas have strict protection laws (IUCN management category I), while others permit a variety of human activities (IUCN management category VI), and others have no IUCN ranking (Table 1). The percentage of protected areas under the various IUCN categories varies geographically: 31% of the protected areas in the polar areas are in either the IUCN category I or II, while 5% of the protected areas in Africa and Europe are designated in IUCN categories I or II.

The governance of the protected areas is primarily based on government protected areas (79% of protected areas), followed by private (5%), shared (3%), and indigenous peoples and local communities (<1%); 12% of the protected areas do not report their governance structure. The governance of the protected areas also varies geographically (Table 1). For example, governance in 87% of the protected areas in Europe is by government, while in West Asia and Polar regions these percentages drop to 43% and 49%, respectively. Private governance is greatest in North America (21% of protected areas), while the highest percentages for shared governance (8–9%) are in Asia and the Pacific, North America, and West Asia. Governance by indigenous people and local communities is greatest in Latin America and the Caribbean (9%), with all other regions having 0–3% of their protected areas falling into this category. Although these governance data are informative, it is important to note that in four regions, more than 30% of the protected areas did not have governance information reported (Polar: 51% of protected areas, West Asia: 46%, Africa: 33%, and Latin America and the Caribbean: 32%).

Biodiversity Conservation

The percentage of terrestrial land and marine areas that have been designated as protected has increased during the past several decades. Although multiple studies have shown that protected areas often aid in biodiversity conservation, the global rate of species declines has consistently increased and almost half of terrestrial tropical protected areas have experienced biodiversity loss during the past couple of decades (Laurance et al., 2012). Therefore, there remains a great need to expand, improve upon, and complement the current protected areas, with an eye to conserving biodiversity.

In October 2010, the Convention on Biological Diversity's Conference of the Parties set forth the Aichi Biodiversity Targets as part of the Strategic Plan for Biodiversity 2011–20. These 20 targets address five strategic goals associated with reducing biodiversity loss. These targets range from increasing people's awareness as to why biodiversity is important, and how people can work on conserving biodiversity and use biodiversity sustainably (Target 1) to mobilizing financial resources to carry out the plan (Target 20). Aichi Target 11 specifically addresses protected areas: this target is to protect 17% of terrestrial land and inland waters, and 10% of coastal and marine areas by 2020 (<https://www.cbd.int/sp/targets/>).

However, some argue that Aichi Target 11 is not sufficient for biodiversity conservation (Dinerstein et al., 2017). Venter et al. (2014) found that only 15% of threatened vertebrates have adequate coverage from protected areas: 17% of threatened vertebrates

were not located within a protected area, and overall, 85% of threatened vertebrates are not covered by protected areas to an extent great enough to provide future protection. Marine protected areas can positively impact biodiversity conservation, but staff and budgetary limits can negatively impact conservation measures (Gill et al., 2017). Therefore, the expansion and creation of new protected areas must be strategically done so that biodiversity is protected to a greater extent (Gill et al., 2017; Venter et al., 2014). Although protected areas can be terrestrial or marine, this current encyclopedia article focuses on terrestrial protected areas and the relationship between them and terrestrial anthromes.

Anthromes

Ecologists typically classify regions into biomes, based on vegetation and climate patterns. However, these biome classifications rarely take into consideration the impact that humans have on ecosystems and biodiversity, specifically the alterations that humans have made to biomes. Human behavior can be an important factor in species distribution patterns; for example, Brum et al. (2013) found that land use was a better predictor than climate for amphibian distribution.

The concept of anthromes, or anthropogenic biomes, was introduced by Ellis and Ramankutty (2008). Anthromes are determined by factors such as human population, land cover, and land use. To date, anthromes primarily have focused on terrestrial regions. During the past decade, researchers have used anthromes to address questions related to how humans impact global ecosystems, and the connections between ecosystems and humans. Overall, protected land has a smaller human footprint than non-protected land, but almost 60% of protected land experiences some extent of human pressure (Jones et al., 2018). Furthermore, more than 50% of protected areas consist solely of land that is under intense human pressure; only 10% of protected areas are free of human pressure (Jones et al., 2018). Therefore, it is important to examine protected areas in light of the human presence and pressure on these protected areas.

The anthrome categories may vary in number, depending on the analysis. The data presented in this overview follow the second version of the anthrome data set (Anthromes V2; Ellis et al. 2010). Anthrome classes provide a different view of a geographic area, when comparing these anthromes to biomes (Fig. 2). This is not to say that one data set is superior to the other; using a combination of data sets can help further discern patterns in species distributions, biodiversity, and conservation, especially in the context of the role that humans have played in shaping and being shaped by the local environment.

Protected Areas and Anthromes

Anthromes are not equally protected: remote woodlands, wild treeless and barren, and wild woodlands have the largest percent of their areas protected, while irrigated villages, rice villages, and residential irrigated croplands have the least protection (Martin et al., 2014), and areas that are not as populated by humans typically have greater protection than anthromes that are more populated (Martin et al., 2014). Furthermore, anthromes have not received equal attention when it comes to research studies; urban, mixed settlements, and residential woodlands have been the focus of the most studies, while rice villages, remote rangelands, and irrigated villages have been studied the least. When Martin et al. (2014) examined the prioritization of protection for an area (based on biodiversity hotspots), they found that anthromes that had a higher prioritization had less protection.

Anthrome Change: 1700–2000

As human population has increased, the pressures that humans put on their environment have intensified. By mapping data from Ellis et al. (2010), one can see that in 1700, the most prevalent anthromes at a global scale were wild woodlands (29% of terrestrial areas), wild treeless and barren lands (27%), inhabited treeless and barren lands (14%), and populated woodlands (13%). By 2000, the most prevalent anthromes at a global scale were relatively similar, with the two most-prevalent anthromes being the same as in 1700. However, the percentage of area making up wild woodlands and wild treeless and barren lands was approximately half of the 1700 values: wild woodlands (19%), wild treeless and barren lands (15%), remote rangelands (13%), and populated rangelands (9%). The similarities in most-prevalent anthromes are due to the large land masses in the high latitudinal regions and the Sahara Desert in Africa where the extent of direct human influence on the land has not been as great as it has been in other regions. The differences between 1700 and 2000 are much more evident when examining areas in mid- and low-latitude regions (Fig. 3A and B).

The extent to which anthromes have changed in mid- and low-latitude regions is evident when examining the global data, as well as in areas inside and outside of protected areas. Protected areas often are subjected to less land cover change than nonprotected areas, and this pattern is illustrated in the case of some, but not all, protected areas. For example, in an area of central and eastern Brazil, covering areas that include the Amazon and the Atlantic Forest, some of the indigenous areas in the Amazon have not encountered as large a change in anthromes as areas outside of these protected areas, or compared with protected areas in the Atlantic Forest region (Fig. 3C and D). These differences can be seen visibly, even before the differences are quantified. However, as evident from these examples (Fig. 3D), current protected areas in Brazil represent a range of anthromes, including ones that have been moderately-to-intensely used by humans.

Fig. 2 Terrestrial biomes (A) and terrestrial anthromes (B) differ in the data they provide. In an areas of East Asia (*dashed box*), there are close to 10 anthromes noted (C) while the same geographic region is noted by three biome types (D). Consider having one large map to show the global patterns, but then subset boxes to show what a small area looks like when using biome data, anthrome data, and satellite imagery. Data sources: World Wildlife Fund; Ellis, E. C., Klein Goldewijk, K., Siebert, S., Lightman, D., and Ramankutty, N. (2010) Anthropogenic transformation of the biomes, 1700 to 2000. *Global Ecology and Biogeography* **19**, 589–606.

Fig. 3 Terrestrial anthromes have changed from 1700 (A) to 2000 (B), especially in mid- and low-latitude regions. These changes are evident inside and outside of protected areas, including in a subset (C and D) of the Amazon and Atlantic Forest regions in Brazil. In 1700, wild woodlands (67% of the geographic area mapped; C) and remote woodlands (18%) dominated the landscape, including in areas that eventually became protected areas (delineated by the *black polygons*). By 2000 (D), much of the wild woodlands and remote woodlands, especially outside of the protected areas located in the northwestern area of the sample (in the Amazon), had been converted to populated rangelands (39%) and residential rangelands (12%), with wild woodlands (11%) and remote woodlands (7%) representing a much smaller area than in 1700. These areas where the anthromes changed from 1700 include localities that are currently designated as protected areas. Data sources: Ellis, E. C., Klein Goldewijk, K., Siebert, S., Lightman, D., and Ramankutty, N. (2010) Anthropogenic transformation of the biomes, 1700 to 2000. *Global Ecology and Biogeography* **19**, 589–606; UN Environment WCMC.

Roads

Another variable to consider when studying the extent to which biomes are impacted by humans is the presence of roads: although ~80% of the terrestrial regions of Earth do not have roads, the roads that do exist split the land cover into many patches, and more than 92% of these patches are $\geq 100 \text{ km}^2$ (Ibisch et al. 2016). These findings have implications for the protection and conservation of anthromes. For example, Ibisch et al. (2016) found that remote rangelands (16.7%), wild woodlands (16.7%), and wild treeless and barren lands (14.2%) had the highest percentage of roadless areas (defined as roads and the 1-km buffer surrounding the roads), while urban (0.05%), mixed settlements (0.4%), pastoral villages (0.5%), and residential irrigated croplands (0.6%) had the smallest percentage of roadless areas in their anthromes.

In summary, about two-thirds of the roadless areas were represented by remote and unmodified anthromes, but anthromes with a heavier human influence, such as rangelands, also attained a relatively high percentage of roadless areas in some geographic locations (Ibisch et al. 2016). When examining the results on a country basis, continental United States, southern Canada, western Europe, and Japan had the smallest percentage of their areas considered roadless. On a continent-level, Africa, South America, Australia, and Asia all had more than 87% of their land as roadless, while Europe (41.6%), North America (61.4%), and Oceania (63.9%) had a notably smaller percentage of their areas considered as roadless.

Green List of Protected and Conserved Areas

The IUCN Green List of Protected and Conserved Areas highlights 45 sites in 14 countries that have been deemed to be strong positive examples in the management and governance of protected areas and conserved areas. Of these 45 sites, 32 were terrestrial sites with geographical extents delineated in the World Database of Protected Areas and with anthrome data covering the extent of the protected areas (Table 2).

When the most-common anthrome in each protected area was noted, there was quite a range of anthromes listed: 12 anthromes were the most-common anthromes in at least one of these 32 sites. Of these 12 anthromes, residential rainfed croplands (19% of these 32 protected areas) was the most-common anthrome for the greatest percentage of the protected areas on the IUCN Green List of Protected and Conserved Areas (Table 2; Fig. 4). Following residential rainfed croplands were residential woodlands (13%), urban (9%), remote rangelands (9%), populated rangelands (9%), populated woodlands (9%), residential rangelands (6%), remote woodlands (6%), rainfed villages (6%), inhabited treeless and barren lands (6%), wild treeless and barren land (3%), and populated croplands (3%). Some of the protected areas from the IUCN Green List of Protected and Conserved Areas were relatively small, so the resolution of the anthrome data (Ellis et al. 2010) did not account for the small areas or heterogenous areas within a small protected area. Furthermore, some terrestrial protected areas were on islands, and the geographical extent was not covered in the Ellis et al. (2010) anthrome data set.

Of these 32 terrestrial protected areas from the Green List of Protected and Conserved Areas, the IUCN categories for the reserves included Ia (3% of the 32 terrestrial reserves), II (31%), IV (19%), V (16%), and VI (3%). There were no protected areas in the IUCN categories Ib or III, and 28% of the protected areas did not have an IUCN category listed (because it was considered not applicable or the category was not reported to the World Database of Protected Areas). When the anthromes were ranked by the extent of human impact (lowest: inhabited treeless and barren lands; greatest: urban; see Fig. 2B legend for the anthrome categories), there was no a relationship between IUCN category and anthrome type (Pearson's Correlation: $P = .21$, $n = 23$, $P = .34$) for the 23 protected areas with an IUCN ranking. For example, the only protected area with an IUCN category Ia classification had residential rainfed cropland as its most-prevalent anthrome, while the only protected area with an IUCN category of VI had remote woodlands as its most-prevalent anthrome.

Of the 32 protected areas included on the Green List of Protected and Conserved Areas, 72% are governed by governments, 3% are joint governance, 9% are nonprofit governed, and 16% have no information reported regarding governance. All three of the nonprofit-governed protected areas represented on the list have residential rangelands or residential rainfed croplands as the primary anthrome represented. The one joint-governed protected area is primarily urban. The government protected areas range from inhabited treeless and barren lands as the primary anthrome (lowest human influence) to rainfed villages (greatest human influence for the current data set) as the primary anthrome.

Half Earth, Nature Needs Half, and Other 50% Proposals

A recent set of proposals have been made that focus on increasing the area of protected areas to 50% or more of Earth (terrestrial as well as marine ecosystems). These proposals include Half Earth (<https://www.half-earthproject.org/>) and Nature Needs Half (<https://www.half-earthproject.org/>), but there have been scientifically-based calls for 50% protection of ecosystems by a number of studies dating back several decades (see review in Dinerstein et al. 2017). Overall these proposals address the challenge of conserving biodiversity while meeting human demands (e.g., food, shelter).

Is it feasible to protect 50%? In an analysis of 846 terrestrial ecosystems on Earth, Dinerstein et al. (2017) found that 12% of the ecosystems were more than 50% protected, 37% were less than 50% protected but had the potential to reach 50%, and 24% are in danger of being destroyed. Therefore, if these 37% were upgraded to 50% protected, the goal could be reached. However, a goal of 50% protected is not necessarily simple in order to maximize biodiversity, as one needs to consider which areas should be protected

^aIUCN green list of protected and conserved areas: <https://www.iucn.org/theme/protected-areas/our-work/iucn-green-list-protected-and-conserved-areas/iucn-green-list-areas> and World Database of Protected Areas (WDPA; <https://www.protectedplanet.net/>). Four reserves in China are not included in the WDPA data set.

^bAnthromes are designated for terrestrial areas, so marine areas do not have anthrome data listed here. Some island reserves also do not have anthrome data available. When only one anthrome is listed for a site, the site consists 100% of the listed anthrome. Data source: Ellis, E. C., Klein Goldewijk, K., Siebert, S., Lightman, D. and Ramankutty, N. (2010). Anthropogenic transformation of the biomes, 1700 to 2000. *Global Ecology and Biogeography* **19**, 589–606.

^cDue to the small size of the reserve (0.7 km²), the anthrome data set's resolution did not classify the area as being forested.

^dOnly a small percentage of this protected area is terrestrial; most of the protected area is marine.

^eThis site was listed in 2019 and as of July 2019 there are no accompanying data available on the IUCN or Protected Plant websites.

(and where), as results could vary based on which regions are protected (Ellis and Mehrabi, 2019). In addition, there are questions as to how the protected areas are governed, to what extent the protected areas allow for movement between reserves (which is important for migrating species as well as species that are impacted by climate change), the extent to which there multi-use areas in the protected area, to what extent agriculture is displaced, who has sovereignty over the land, and how to cover the operating costs of the protected areas (Ellis and Mehrabi, 2019).

How Are We Doing?

The majority of the current protected areas were created during the 20th century. The extent of terrestrial ecosystems has approximately doubled since the early 1990s, and continues to increase. There have been conservation successes through these protected areas, with overall global patterns indicating that species richness and abundance are higher inside protected areas, compared to outside of these areas (Gray et al., 2016). However, there can be great variability in the success of a protected area, and many protected areas have minimal funding.

Distribution and Management

Protected areas are not always representative of global ecosystems. Often these reserves are geographically remote or represent areas that humans have not wanted to use for commercial purposes, and they are typically not located in areas with high concentrations of threatened vertebrate species (Venter et al. 2017). The location of reserves does not always match with areas with high phylogenetic diversity (Daru et al., 2019). Furthermore, the locations of protected areas do not often match with the areas that are used by species

Fig. 4 Twelve anthromes were the most-common anthrome for at least 1 of the 32 terrestrial sites from the IUCN Green List of Protected and Conserved Areas as of July 2019. Of these 32 sites, residential rainfed croplands represented the greatest percentage of sites: 19%. Data sources: IUCN Green List of Protected and Conserved Areas: <https://www.iucn.org/theme/protected-areas/our-work/iucn-green-list-protected-and-conserved-areas/iucn-green-list-areas> and World Database of Protected Areas (WDPA); <https://www.protectedplanet.net/>; Ellis, E. C., Klein Goldewijk, K., Siebert, S., Lightman, D. and Ramankutty, N. (2010). Anthropogenic transformation of the biomes, 1700 to 2000. *Global Ecology and Biogeography* **19**, 589–606.

that migrate; for example, less than 10% of migratory bird species are covered by protected areas throughout their range (Runge et al., 2015). It is important to strategically place new protected areas in locations where biodiversity conservation may be maximized.

Protected areas also do not have equal protection, even on paper. Although protected areas are distributed across the globe, and in many cases having protection makes it more likely that the land cover will not be modified, more often than not these protected areas are found in areas that are less likely to be subjected to land cover change than other areas. For example, Joppa and Pfaff (2009) found that most national protected areas often are located in areas with higher elevation, increased slopes, and farther from roads and cities; Venter et al. (2014) found that protected areas are often areas that are less expensive to protect, and they are not necessarily areas of high priority for biodiversity protection (as priority areas tend to be more expensive to protect). As a result, there are concerns that protected areas often protect more marginal lands. Furthermore, reasons for the placement of the current protected areas vary greatly based on location.

Furthermore, many protected areas do not receive adequate funding, and they can be hampered by poor management of the areas (Pringle, 2017). Strong management of the protected areas, including having people present in the protected reserve to provide protection of the reserve, was found to be a predictor of a successful reserve (Laurance et al., 2012). One may learn more about management effectiveness, by accessing the Protected Areas Management Effectiveness (PAME) data and reports. The framework for assessment includes taking into consideration management design and planning, management adequacy and appropriateness, and management delivery such as outputs and outcomes.

Biodiversity Conservation

Although one of the primary goals of protected areas is to conserve biodiversity, the rate of species declines has consistently increased. Furthermore, human pressure on protected areas increased over a 15-year period in the 1990s and 2000s, particularly in Southeast Asia, Latin America, Sub-Saharan Africa, and Euro-Asia (Geldmann et al., 2014). Protected areas without an IUCN ranking had greater increases in human pressure, followed by protected areas in category IV. Jones et al. (2018) found that approximately one-third of protected areas are impacted by human pressure; since 1992, 55% of the protected areas have had an increase in human pressure. They found that large protected areas with strict protections had the least amount of human pressure.

There are several examples of protected areas that represent ecosystems that had been degraded and restored (Pringle, 2017), highlighting the importance of considering protected areas and human activities together. Furthermore, Gray et al. (2016) found that species richness and abundance was higher inside even some of the protected areas that had been impacted by human land use (e.g., plantation and cropland). Therefore, understanding the impacts of protected areas on anthromes can be important. Furthermore, given the amount of land that is impacted by humans, taking anthromes into consideration can be important in determining the overall conservation situation.

Pringle (2017) highlights “eight pillars of upgrading protected areas”: (1) “Protect remaining refuges and harness nature’s resilience”—allow natural processes to work, and realize that the restored ecosystem may differ from the original ecosystem;

(2) “Upsize and interconnect”—consider expanding protected areas by increasing their boundaries; (3) “Be long-term and local”—the importance of having a core, local team that can work to improve the protected area; (4) “Pay the opportunity costs”—work with constituencies to increase support for the protected areas; (5) “Develop creative financial strategies”—consider varied financial strategies, such as public-private partnerships; (6) “Know thy biodiversity”—the importance of knowing which species are located within the protected area; (7) “Be adaptable”—realize that some plans may work better under certain situations, and goals may differ depending on the constituents; and (8) “Involve young people”—get children involved and invested in nature.

Socioeconomic Considerations

As outlined above, humans have played a significant role in shaping the anthromes, as well as in the establishment, management, support, and, in some cases, degradation, of protected areas. The earlier sections mention the various roles that humans play in shaping protected areas and anthromes, but it is important to specifically consider how social objectives and economics have shaped (and will shape) protected areas and anthromes. Sometimes the studies of protected areas have a sole focus on biodiversity metrics, excluding any considerations of socioeconomics. Many scholars have argued that it's very important to take economic and social issues into consideration when establishing and managing a protected area. Protected areas should benefit biodiversity conservation and humans. Several of the pillars highlighted by [Pringle \(2017\)](#) specifically address the role that various constituents can play in sustaining a successful protected area; these pillars also stress the importance of understanding that the effort in sustaining a successful protected area will be a long-term investment by people. As the number of protected areas increase, it is very important to ensure that humans, as well as biodiversity, benefit ([Ellis and Mehrabi, 2019](#)).

Moving Forward

As discussed earlier, the type of management that a protected area is under is often related to the success of the reserve. In fact, [Adams et al. \(2019\)](#) found that using funding for management provided increased benefits compared to using the funds to expand the extent of the protected areas. With the call for an increase of the percentage of the Earth that is under protection, some argue that it's increasingly important to focus on the management of the current protected areas, as well as consider the management of soon-to-be created reserves, in order to reap the maximum benefits of the reserve. In other words, simply expanding the number and size of protected areas is not necessarily going to help reach the goal of conserving biodiversity and ensuring that human needs are met. Without investment into management, biodiversity benefits may not meet their potential. Therefore, some propose that protected area expansion, although important, should be accompanied by appropriate management in the already-established protected areas, as well as those protected areas that are being designated in the near future to meet specific targets.

To meet the 17% goal of Aichi Target 11, almost 2 million km² (representing 190 terrestrial ecoregions in 114 nations) will need restoration ([Mappin et al., 2019](#)). Although restoration of land that has been slightly modified is seen to be possible, there are ecoregions that have been so heavily modified that restoration will take great effort. Therefore, there needs to be a concentrated effort to evaluate the potential of restoration for particular ecoregions, and identify specific ecoregions in specific locations where there is a higher likelihood of success.

[Ellis and Mehrabi \(2019\)](#) recommend that people consider the Half Earth concept as a Whole Earth project, that people should be encouraged to work to protect biodiversity at multiple scales (local, regional, and global) instead of thinking about protection as two halves: “nature’s half” and “human half.” This argument is supported by the fact that, as discussed above, humans have impacted a majority of the terrestrial surface of Earth already. By including anthromes in analyses, one can better understand what the primary actions of humans are (and have been) based on geographical location. For example, it could be helpful in tracing the history of the geographical location, noting to what extent the anthromes have changed in particular locations. Furthermore, analyses could reveal if there are geographical patterns in regards to the spatial distribution of anthromes, the history of the current anthromes, and the distribution of particular species. Such considerations can be important when thinking about biodiversity conservation overall, but particularly when certain species are of conservation focus. Species have a range of habitat requirements, and some are more sensitive to particular types of human activities than to other human activities. By having a better understanding of the anthromes in a protected area, as well as outside a protected area, could help with plans to conserve biodiversity.

Conclusion

Given that the majority of the land on Earth has been impacted to some extent by humans, it is important for there to be more widespread consideration of how humans and the natural systems in which humans have evolved are interconnected. Solely

designating areas as protected areas will not necessarily conserve biodiversity for the future; the protected areas need to be ecologically relevant in order to maximize biodiversity conservation. Because the percentage of land that is considered pristine, with little to no human impacts, is minimal when compared to all terrestrial areas on Earth, and the majority of protected areas also are impacted by humans, addressing conservation issues such as biodiversity decline, as well as understanding current and future impacts of climate change on biodiversity, will require natural scientists, social scientists, policy makers, lawmakers, educators, and humans in general to take a look at the natural system in which we live, and truly think about how our behaviors and actions impact the rest of the system, as well as how the natural system impacts our lives.

Abstract

Humans have altered the majority of Earth's terrestrial surface, yet some places still remain relatively undisturbed by modern society. These wilderness areas contain the most intact ecosystems on Earth. Here, we review the emerging evidence that wilderness areas are exceptionally important relative to more degraded ecosystems for biodiversity conservation (e.g. halving species extinction risk), Earth system functioning (e.g. supporting continental scale hydrological cycles), and for supporting the cultural integrity of many indigenous communities worldwide. We then describe the current state of wilderness conservation and mapping. Despite their immense value, wilderness areas are being rapidly lost, are under protected, and are almost completely overlooked in global environmental policy. Our window of opportunity to safeguard Earth's last wilderness areas and their unique values is closing fast, but through a combination of smart policy changes and immediate large-scale conservation efforts, we can still secure them for future generations.

"If future generations are to remember us with gratitude rather than contempt, we must leave them something more than the miracles of technology. We must leave them a glimpse of the world as it was in the beginning"

—Lyndon B. Johnson

Wilderness Defined

Humans have significantly altered the majority of Earth's terrestrial area (Ellis and Ramankutty, 2008; Venter et al., 2016b). Land uses such as pasture and cropping are now extensive (Ramankutty et al., 2008; Alkemade et al., 2013), industrial infrastructure, forestry, road networks and urban areas are proliferating (Seto et al., 2012; Ibisch et al., 2016), and activities such as the harvesting and hunting of wild plants and animals are highly unsustainable (Ripple et al., 2016). The increase in these "human pressures" has come at the expense of previously wild places, causing biodiversity and the condition of ecosystems to decline worldwide (Ellis et al., 2010; Barnosky et al., 2012; Ceballos et al., 2017). However, human pressure varies across Earth's surface, and some corners of the planet remain undisturbed by the impacts of modern society. These places can be considered wilderness, and contain the most intact ecosystems on Earth (Lesslie et al., 1988; Mackey et al., 1998; Watson et al., 2016).

Wilderness does not mean "pristine" or "untouched" because nowhere meets this standard in an era of human forced climate change and global pollution (Barnes et al., 2009; Scheffers et al., 2016). Wilderness areas are also not exclusive of people, as human presence can and does occur within them, provided human impacts are minimal and do not compromise the ecological integrity of the area (Mackey and Claudie, 2015; Larsen and Jaeger, 2017). Human societies have occupied all continents except Antarctica and influenced the environment much more than previously thought. For example, prehistoric humans farming domesticated plants shaped tree communities in some of the remotest parts of the Amazon rainforest (Levis et al., 2017). However, the ecological

footprint of these societies is challenging to measure and is likely minimal compared to the environmental impacts of modern industrial land-uses (Klein et al., 2009; Newbold et al., 2016).

There is room for debate as to what truly constitutes wilderness, and a variety of definitions have been developed by governments, non-government organizations and researchers, but there is no global consensus on the definition (Hawes et al., 2018). Most prominent definitions have several attributes in common; they identify wilderness by setting minimum thresholds of naturalness (the extent to which an area is unaffected by human pressures or to which it retains its ecological integrity), remoteness (from infrastructure and landscape disturbance), and size (e.g. a minimum contiguous area) (Lesslie et al., 1988; Mackey et al., 1998; Hawes et al., 2018). Here, we follow these definitions and consider wilderness areas as “large, ecologically intact landscapes”, and when mapping wilderness areas, set minimum thresholds on their size and naturalness to provide a precise definition (Allan et al., 2017).

There have also been deliberations about whether the term wilderness is still relevant given humanity’s ubiquitous fingerprint (Cronon, 1996). However, regardless of how wilderness is defined, it is clear that large intact ecosystems hold an exceptional range of environmental and cultural values that are being lost in more human modified, fragmented, and ecologically degraded landscapes (Freudenberger et al., 2012; Lovejoy, 2017; Watson et al., 2018a). We now describe these values, and their important contribution to human well-being and the health of the planet, demonstrating that protecting wilderness is critical for averting the biodiversity crisis, addressing anthropogenic climate change, ensuring ecosystem service provisioning, and maintaining the world’s human cultural diversity.

The Exceptional Values of Wilderness

Biodiversity Conservation

Humans are currently driving a biodiversity extinction crisis. Species populations are declining, their ranges contracting, and extinction rates are 1000 times higher than background levels (Pimm et al., 2014; Ceballos et al., 2015, 2017). When it comes to averting this crisis, protecting wilderness areas is critical because they still support high levels of species richness and endemism, and contain large populations of common but declining species (Mittermeier et al., 2003; D’agata et al., 2016; Watson et al., 2016). Wilderness areas are the only places that still contain species assemblages at near natural levels of abundance, especially for large mega-fauna (Mittermeier et al., 2003; Ripple et al., 2015), and wide ranging and migratory species (Klein et al., 2009; Bauer and Hoyer, 2014; Lamb et al., 2018; Photopoulou, 2018). They also support the ecological processes that sustain biodiversity over evolutionary time-scales such as trophic relations at regional scales and animal dispersal and migration (Soule et al., 2004).

Perhaps the best quantification of the value of wilderness for biodiversity is a recent study by Di Marco et al. (2019), who showed that species in wilderness communities are—on average—half as likely to go extinct as those in non-wilderness communities. This demonstrates how wilderness areas buffer species against extinction. Ensuring large wilderness areas are protected is also essential because smaller patches of habitat tend to lose many of their species over time (MacArthur and Wilson, 1967; Soule et al., 2004). This is especially true for top predators; whose populations frequently collapse in isolated habitat patches that are too small or suffer hunting from humans along the periphery. As such, wilderness areas are key refuges for species that are sensitive to exploitation by, or conflict with humans, which includes many charismatic carnivore species (Gibson et al., 2011; Ripple et al., 2014). As disturbance sensitive species disappear from human dominated landscapes, wilderness areas are rapidly becoming their last strongholds. These wilderness refugia serve as important reservoirs of genetic information, and sources of populations and propagules for restoration and rewilding efforts (Ceaşu et al., 2015b). They are also places where nature can be studied free from human disturbance, serving as important baseline references of ecological and evolutionary function.

Notably, wilderness areas are not safe from all possible threats to biodiversity. For example, invasive species can spread into wilderness areas jeopardizing biodiversity in these places. Wilderness areas will not necessarily protect species from climate change, and conditions in many of the most remote intact areas globally are changing rapidly. However, wilderness areas do confer many benefits to species in the face of climate change that other more degraded areas do not. Wilderness refuges are especially important given rapid climate change, because they allow species to adapt by housing large populations (allowing for local genetic adaptation), and enabling species to disperse to favorable climates without having to cross human barriers (Scheffers et al., 2016; Tucker et al., 2018). There is also evidence that the impacts of climate change on ecological communities are felt more severely in degraded and fragmented landscapes than intact ones, and this holds for many ecosystems, including rapidly changing ones such as the arctic (Hansen et al., 2001; Djoghla, 2008; Mantyka-Pringle et al., 2012; Watson et al., 2018a). As such, proactively securing the remaining wilderness is increasingly seen as fundamental to global efforts to avert the biodiversity extinction crisis (Watson and Venter, 2017).

Ecosystem Services

Unimpeded by human activity, wilderness areas continue to support the natural evolutionary and ecological processes that underpin life on Earth, providing a suite of high value ecosystem services (Klein et al., 2009; Watson et al., 2009; IPCC, 2014). For example, wilderness areas regulate climate regimes and hydrological cycles at multiple scales (Salati et al., 1979; Furniss et al., 2010). This includes generating rainfall, for example air that passes over ecologically intact tropical forests produces twice as much rain as degraded forests or converted land (Sheil and Murdiyarso, 2009). Evapotranspiration also has a cooling effect

that buffers the temperatures of local climates during heatwaves (Deo et al., 2009; Ahlström et al., 2015). The quantity of ecosystem services provided also increases with the size of a wilderness area (Wright et al., 1999; Chagnon and Bras, 2005), and in many cases is a direct result of that size because it allows wilderness areas to act as complete self-organizing systems (Sanderson et al., 2002). This has major implications for conserving wilderness areas because damage in one part of the system can affect the functioning of the entire system (Laurance, 2005; Peres, 2005). For example, it is estimated that the Amazon requires at least 75–80% of its forest cover to retain its hydrological cycle (Sampaio et al., 2007; Lovejoy and Nobre, 2018), and therefore must be conserved almost in its entirety (Laurance, 2005).

Proactively protecting carbon rich wilderness also makes a significant contribution to stabilizing atmospheric CO₂ levels, and achieving global climate mitigation goals. This is because ecologically intact ecosystems have a greater capacity to sequester and store carbon than degraded ecosystems (Mackey et al., 2013; Avitabile et al., 2016). For example, one third of the total global stock of forest biomass carbon is stored in the boreal forest biome, the most intact ecosystem on the planet (Pan et al., 2011), and the Amazon region stores nearly 38% of the above ground carbon stored in woody vegetation in tropical America, Africa and Asia combined (Walker et al., 2014). Beyond forests, intact coastal systems including mangroves, salt marshes, and seagrasses have an exceptional capacity to sequester and store carbon (Fourqurean et al., 2012). However, when degraded, they quickly change from carbon sinks to major carbon sources (Howard et al., 2017). The same applies for other intact ecosystems, for example, slight degradation of intact forests can cause substantial carbon release (Houghton, 2012; Chaplin-Kramer et al., 2015; Watson et al., 2018a; Maxwell et al., 2019).

Wilderness areas have an important role to play in the fight against anthropogenic climate change beyond storing and sequestering carbon. In many situations they provide humanity with a direct defense against extreme climatic events such as floods, sea level rise and cyclones (The World Bank, 2009). For example, intact mangroves, grasslands, coral reefs, wetlands and forests are humanity's best protection against floods and storms (Bradshaw et al., 2007; Ferrario et al., 2014), with highly intact ecosystems providing stronger protection than degraded ones (Alila et al., 2009; Brookhuis and Hein, 2016). The intact mangroves of the Tamil Nadu coast in India, for instance, significantly reduced damage to human structures following the tragic Indian Ocean Tsunami of December 26th 2004 (Alongi, 2008).

Securing intact ecosystems is also recognized as humanity's most cost-effective defense against climate change (The World Bank, 2009; Martin and Watson, 2016), and is often orders of magnitude cheaper than engineered solutions such as building sea walls instead of protecting intact reefs, salt marshes and mangroves (Shepard et al., 2011; Jones et al., 2012). Recent analyses estimated that coral reefs save Indonesia, the Philippines, Malaysia, Mexico and Cuba over 400 million USD annually through flood avoidance (Beck et al., 2018), and that wetlands saved the United States over 625 million USD in flood damages following hurricane Sandy in 2012 (Narayan et al., 2017). Perversely, ecosystems such as coral reefs are often destroyed or degraded in the process of building sea walls and protective infrastructure (Grantham et al., 2011; Maxwell et al., 2015).

Human Cultural Diversity

Wilderness areas are home to many of the most politically and economically marginalized indigenous communities on Earth (Gorenflo et al., 2012; Schwartzman et al., 2013). These peoples number in the hundreds of millions and are reliant on the ecosystem services provided by intact marine and terrestrial ecosystems for essential resources such as food, water, and fiber (MEA, 2005). Securing wilderness is central to reducing poverty and marginalization of these people's, and for achieving many United Nations Sustainable Development Goals (SDG's) such as human well-being, clean water, reduced inequalities, peace and justice, as well as the biodiversity and climate goals (United Nations, 2015). Many indigenous peoples have inhabited wilderness areas for millennia, developing strong bio-cultural connections to the land (Larsen and Jaeger, 2017). In these cases, securing wilderness is critical for securing their long-term cultural integrity.

There have previously been conflicts between the people living in wilderness areas and conservationists, with wilderness debates historically framed as mutually exclusive choices between conservation and development. However, wilderness conservation thinking has evolved, and it is increasingly recognized that there are common interests between conservationists and local communities in light of growing human pressure on the natural environment (Venter et al., 2016b; Larsen and Jaeger, 2017). The sustainable livelihoods and cultural integrity of many indigenous communities are often threatened by the same industrialized development pressures that threaten biodiversity and wilderness areas (Boff, 2002; Sutherland, 2003). For example, human cultural and language diversity, which co-occurs with biodiversity, is declining outside of wilderness areas (Gorenflo et al., 2012; Amano et al., 2014). There are also cases of violent conflict between economic development and indigenous peoples (Simmons, 2002; Finer et al., 2008), including the mass-murder of uncontacted Amazonian tribes by gold miners (Darlington, 2017), and inter-tribal warfare spurred on by oil exploration in Ecuador (The Economist, 2013). Protected areas, indigenous protected areas, and other land-use designations preventing industrial development can act as important buffers protecting indigenous people and ensuring they have the wild spaces required to maintain their cultures. As such, there are opportunities to integrate both nature and culture in the conservation of large wilderness areas.

The State of Wilderness Conservation

Even though most definitions of wilderness lack precision, the broad concept of wilderness as still proved valuable, motivating conservation efforts for centuries. For example, wilderness inspired the writings of Audubon, Muir, Leopold and others, whose

works form the moral foundations of our field. Leopold in particular recognized that landscapes are systems, which if functioning properly, support the processes that generate soil, water, and life. Leopold compellingly articulated this ethical philosophy in his 1949 classic *A Sand County Almanac*, popularizing the idea that wilderness areas have value if preserved in their wild state, and inspiring generations of conservationists. Wilderness protection was also the inspiration for Yellowstone, the world's first national park, designated in 1872 in the United States. The national park model spread worldwide and still forms the backbone of conservation efforts today.

Despite the historical importance of wilderness, and the emerging scientific consensus showing that intact ecosystems have exceptional ecological values compared to more degraded ecosystems, wilderness areas have been overlooked as conservation priorities in the last few decades (Myers et al., 2000; Brooks et al., 2006). This is partly because the concept of wilderness has come under heavy scrutiny, being described as a human construct, and criticized for promoting a dualistic vision which separates people from nature (Cronon, 1996; Sarkar, 1999). Wilderness conservationists have also been criticized for protecting wilderness from the people who live there, or at their expense, although modern wilderness conservation is now moving beyond this (Mackey and Clau die, 2015; Larsen and Jaeger, 2017). As a result of this criticism, the term wilderness has become controversial and even unmentionable in some circles (Hawes et al., 2018). However, it is important to note that these are not criticisms of wild places and their values, but rather how the term wilderness is defined and used, and how wilderness conservation is carried out (Cronon, 1996).

There is often an implicit assumption amongst conservationists that wilderness areas are free from human impact due to their size, remoteness, and historically limited human presence. As a result, there is a notion that they do not require conservation action, and that conservation resources would be better spent on places that contain high concentrations of threatened species and are thought to be under more imminent threat (Margules and Pressey, 2000; Ricketts et al., 2005). Some conservationists have argued that such reactive approaches to conservation should take precedence over proactive efforts to conserve wilderness (Ricketts et al., 2005; Kareiva and Marvier, 2012; Pressey et al., 2017). However, it is increasingly acknowledged that this is a false dichotomy and conservation requires a balance of both reactive and proactive approaches (Brooks et al., 2006; Cardador et al., 2015; Watson and Venter, 2017; Sacre et al., 2019). Furthermore, until very recently, there were no global analyses of changes in the extent of wilderness areas over time, making it challenging to ascertain how threatened they were.

Information on the condition, threat and protection status of wilderness areas globally was limited because they were not monitored in any regular fashion (Lovejoy, 2017), and the best available maps of global wilderness extent dated back to the early 2000's (Hannah et al., 1994; Sanderson et al., 2002; Mittermeier et al., 2003). Although these maps had proved useful for numerous ecological and conservation analyses (Di Marco and Santini, 2015; Inostroza et al., 2016; Kormos et al., 2016; Payne and Bro-Jørgensen, 2016), they provided a temporally static and much outdated view of wilderness extent (Watson et al., 2009; Laurance et al., 2012, 2014). More recent mapping efforts include global roadless areas (Ibisch et al., 2016), which do not capture many human activities that degrade wilderness areas, and maps of intact forest landscapes (Potapov et al., 2017), which utilize satellite imagery data to assess direct human induced forest structural alterations and fragmentation within forest ecosystems (Potapov et al., 2017).

Despite this lack of up-to-date information, concerns for the safety of wilderness areas were valid considering the widespread pressure humanity is exerting on the natural environment (Steffen et al., 2015; Venter et al., 2016b). Wilderness values can be lost long before habitat has been completely cleared, making wilderness areas particularly vulnerable to pressures such as roads that can have extensive indirect or 'offsite' impacts (Raiter et al., 2014, 2018). These can include the isolation and fragmentation of species populations, increased access for hunting and logging, and increased risk of anthropogenic fire ignition (Mackey et al., 1998; Laurance et al., 2017). In light of growing human pressure globally, there were calls within the conservation community for updated maps of wilderness areas, which would make global assessments of their threat and protection status possible (Bertzky et al., 2013; Kormos et al., 2016).

Recognizing that the lack of up-to-date information on wilderness extent constituted a major impediment to wilderness conservation, we developed new global maps of terrestrial wilderness areas for the years 1993 and 2009 (Fig. 1) (Allan et al., 2017). Utilizing global maps of cumulative human pressure (Venter et al., 2016a), we identified wilderness as all pressure free lands with a contiguous area > 10,000 km² for the years 1993 and 2009. These places represent the most intact ecosystems globally, and are likely to be operating with natural levels of species abundance, community structure and disturbance regimes. We compared the maps of pressure free lands with maps of Earth's Anthropogenic Biomes (Fig. 2), a categorization of Earth's ecosystems based on patterns of sustained direct human interactions (Ellis et al., 2010), and found high congruence between areas identified as wilderness or wild lands in the two approaches (Fig. 3).

The updated wilderness maps enabled an analysis of changes in wilderness extent between 1993 and 2009, which highlighted the catastrophic loss of 3.3 million km² of wilderness (Watson et al., 2016). This is an area greater in size than India, which amounts to a 10% decline in total global wilderness extent over 16 years. To give this context, wilderness loss is occurring four times faster than forest loss globally (Keenan et al., 2015), making wilderness areas some of the most threatened ecosystems on Earth. Only 30 million km² of Earth's terrestrial wilderness remains (23%) and it is rapidly diminishing.

These results highlighted the importance of wilderness conservation, and challenge the widely held perception that wilderness areas are relatively safe from human impacts. Many of the greatest wilderness declines occurred in the Amazon and Central Africa, which are some of the most biodiverse regions on Earth. Furthermore, efforts to conserve wilderness within protected areas between 1993 and 2009 lagged well behind the rate of loss, which was double the rate of protection globally (Watson et al., 2016). Similar mapping has since been carried out for the marine realm (Jones et al., 2018), showing that marine wilderness has almost completely retracted to the polar regions, with only 13% of the ocean still pressure free.

Fig. 1 The 1993 (purple) and 2009 (green) extent of wilderness areas. Data obtained from [Allan et al. \(2017\)](#). Over 3.3 million km² (>10%) of wilderness was lost during this time period ([Watson et al., 2016](#)).

It is also evident that wilderness conservation has received insufficient attention in international environmental agreements and policy deliberations to date ([Watson et al., 2016](#); [Maxwell et al., 2019](#)). Global efforts to achieve ambitious sustainable development and environmental targets have almost completely overlooked the contributions of wilderness areas and their outstanding values ([Watson et al., 2018b](#)). At the international level, there is no formal recognition of the importance of wilderness areas, and no explicit targets for wilderness protection in many of the most powerful multilateral environmental agreements. This includes in the Convention on Biological Diversity ([CBD, 2011](#)), a platform which attempts to coordinate international action to halt or reverse biodiversity loss ([CBD, 2011](#)), and the World Heritage Convention, which aims to protect the world's most valuable natural and cultural sites ([UNESCO, 1972](#)). It is also surprising that the United Nations Framework on Climate Change (UNFCCC) Paris Agreement ignores the important role that wilderness areas play in the fight against climate change ([Maxwell et al., 2019](#)).

The little recognition that wilderness areas have received in policy includes the United States Wilderness Act of 1964 which established standards for protection of wilderness on federal land. A small number of countries including Canada, Australia, Finland and South Africa have followed suit, implementing similar legislation to protect wilderness ([Mittermeier et al., 2003](#)). The International Union for the Conservation of Nature (IUCN) recognizes specific protected areas worldwide that contain wilderness, and includes criteria on size and intactness (Criterion C) in its recently published Global Standards for identifying Key Biodiversity Areas ([IUCN, 2016](#)). Although Criterion C was purposefully designed to protect wilderness, only two sites per ecoregion can qualify based on Criterion C, meaning that only a limited number, albeit a representative sample, of wilderness areas will be captured. Secondly, KBA status does not confer any formal protection for an area—they are conservation priorities that may warrant formal protection ([Smith et al., 2019](#)).

The lack of strong international policy recognition for wilderness areas has significant ramifications for national environmental strategies. The tendency for national biodiversity conservation plans is to focus on remnant habitats and endangered populations of species living in degraded, fragmented and altered ecosystems, with very few nations clearly articulating conservation goals for wilderness areas ([Klein et al., 2009](#); [Watson et al., 2009](#); [Ceașu et al., 2015a](#)). Some wilderness areas are protected under national legislation such as the 1964 United States Wilderness Act, which formally defines and protects wilderness on federal land. However, in most countries, wilderness areas are not formally defined, mapped or protected, and there is nothing to stop them being exploited by national and local governments, private business, and civil society.

Fig. 2 Earth's anthropogenic biomes. Data from Ellis et al. (2010).

Fig. 3 Distribution of Anthropogenic biomes within wilderness areas. Wilderness areas primarily consist of wild woodlands (46%), wild treeless and barren lands (33%), remote rangelands (10%), and remote woodlands (6%).

The implications of the lack of policy recognition for wilderness areas has been noticed, leading to recent and timely calls for international environmental agreements to take a more central role in wilderness conservation (Martin and Watson, 2016; Watson et al., 2016; Watson and Venter, 2017; Barnes et al., 2018; Maron et al., 2018). In particular, there have been calls for the World Heritage Convention, one of the most powerful conservation instruments, to become more engaged in wilderness conservation (Kormos et al., 2016). The role that the World Heritage Convention could play in wilderness conservation is clear (Allan et al., 2018), and represents a substantial conservation opportunity moving forward. It is also in the World Heritage Conventions interests to protect wilderness areas, since the unique values of wilderness are closely aligned with those outlined in the criteria for World Heritage status.

Perhaps the most immediate opportunity to recognize wilderness in policy and set targets for its protection lies with the CBD. The CBD, is a platform that attempts to coordinate international action to halt or reverse biodiversity loss (CBD, 2011), and is one of the most important international agreements relating to biodiversity conservation, with 196 countries currently working towards commitments outlined in the 2020 Strategic Plan. These targets shape the behaviors of individuals, governments and non-government organizations, who appear to take their commitments seriously. The CBD's next Strategic Plan for Biodiversity will take effect in 2020 and run until 2030, representing a crucial opportunity for the conservation community to learn from past mistakes and develop smarter, more ambitious targets (Butchart et al., 2016).

A step towards this could be to radically increase protection coverage targets (i.e. post Aichi Target 11) to a point where they are sufficient to achieve environmental outcomes such as averting the biodiversity crisis and ensuring wilderness areas remain intact (Di Marco et al., 2016; Lovejoy, 2017). Beyond targets for the expansion of protected areas, a new target could also be established for the complete retention of intact natural ecosystems (Maron et al., 2018) (i.e. post Aichi Target 5). This would have to be part of a multi-pronged global strategy with a parallel focus in already degraded landscapes on preventing immediate extinctions and species declines, either via protection or restoration efforts (Allan et al., 2019), and in highly human dominated areas retaining human-nature interactions (Maron et al., 2018).

Conclusion

Human pressure on planet earth will only increase as our population climbs and technology continues its relentless advance. Our window of opportunity to safeguard human well-being and the health of our planet is closing fast. Securing wilderness is an essential step towards this, as these areas house exceptional biodiversity, cultural, and climate regulation values. Wilderness values can only be conserved in their current, naturally functioning state. Once they are degraded, full restoration is near impossible. As President Lyndon B. Johnson observed when he signed the United States Wilderness Act in 1964 "If future generations are to remember us with gratitude rather than contempt, we must leave them something more than the miracles of technology. We must leave them a glimpse of the world as it was in the beginning, not just after we got through with it". "Once our natural splendour is destroyed, it can never be recaptured. And once man can no longer walk with beauty or wonder at nature, his spirit will wither and his sustenance be wasted". Given we have already lost so much, we must grasp this opportunity to secure wilderness before it disappears forever.

Abstract

Dams have been altering riverine ecosystems for as long as humans have been constructing them. In contrast to the river continuum concept that conceptualized rivers as long continuous entities, the serial discontinuity concept (SDC) was developed as a framework for the study of dammed aquatic ecosystems and has proved to be useful in this way. Dams are globally ubiquitous but not evenly distributed geographically, with some countries having far more dams than others, nor within the anthropogenic biomes of the world. The GRanD database reports 6862 large dams worldwide; however, large dams comprise a small portion of dams on the landscape. Many smaller dams can be difficult to account for and in fact one study estimates there to be 16.7 million dams worldwide. In the United States alone, the national inventory of dams reports >90,000 dams. Dams have been demonstrated to have positive impacts on human civilization through their various designed purposes, of which irrigation is the dominant form (38% of large dams). However, dams also have detrimentally affected humans in many ways. For example, dams have displaced an estimated 40–80 million people and are known to increase the incidence of vector borne diseases. In addition to their impact on humans, their influence on ecosystems has been intensely studied and documented, with the results indicating dams are not in the best interests of those systems. Well documented and highly publicized are dams impact on migratory fishes (e.g., salmon species). The heightened awareness by the general public in dams being harmful to aquatic ecosystems and their aging infrastructure has lead to increased interest in their demolition and removal. While dam removal projects are generally considered a boon for ecosystems, their removal can have disadvantageous effects on humans (e.g., economic loss) and therefore all known impacts of dam removals should be considered during this process.

Man-Made Rivers

Lotic ecosystems are often viewed and studied within the context of the River Continuum Concept (Vannote et al., 1980) which conceptualizes them as continuous entities, with ever changing physical and chemical variables that result in predictable physico-chemical attributes and subsequent biological communities along this gradient. This perception is somewhat scale dependent and is applicable at large scales; however, at smaller scales physicochemical and biological patterns may seem random (Stanford and Ward, 2001). These riverine ecosystems are largely products of their watershed, where chemical, geophysical, and biological processes are determined by the river's longitudinal and lateral interconnectedness. Within a watershed, the river's flow is determined by the surrounding hill-slopes; which, through overland and groundwater flow, direct sediments, nutrients, organic matter, and pollutants into the stream channel. The ability for aquatic fauna to move up- and downstream is due to both locomotory ability of the organism and stream morphology (e.g., waterfalls, flow velocity, etc.). Despite this useful and overarching conceptualization, most riverine systems are subject to a variety of discontinuities, most of which are anthropogenic in nature and of which dams are the likely the most ubiquitous and impactful. As such, Ward and Stanford (1983) developed the Serial Discontinuity Concept (SDC) as a theoretical framework for evaluating the influence of dams on lotic systems. Depending on location of dams along a stream's gradient, dams differentially modify physicochemical and biological attributes resulting in conditions that appear more similar to stream reaches some distance up- or downstream of the dam.

Man as the dominant species in ecosystem earth, who by building dams adds to his long-demonstrated capacity for technological change, and who seeks beneficially to integrate that skill with an ongoing process of interaction among human and other elements of the ecosystem. With inspiration and skill, he may mould a better world for his descendants.

SCOPE (1972).

The construction of dams has historically been a socio-economically acceptable practice due to the view that they are necessitated by the need for development of the urban, industrial, and agricultural complex. As human populations have grown so too has the need for increased access to good and services. Dams, with their ability to store water for a variety of reasons but particularly for agricultural irrigation, have acted to facilitate development, which has led to a vast transition of the landscape by increasing human capacity for urbanization, industrialization, and agriculturalization, away from a *natural* landscape and towards anthropogenic

biomes. While dams have arguably improved the human condition for centuries and have certainly been instrumental in guiding the direction of the human condition, they have also been detrimental in many socio-ecological contexts. As such, they are quite likely the most ubiquitous, anthrome enabling human creation.

The number of large dams (Dam with height >15 m or height between 5 and 15 m with a storage capacity of ≥ 3 million m^3) globally as reported by the Global Reservoir and Dam Database (GRaND) (Lehner et al., 2011b) is 6862 and they vary across space (Fig. 1A). Of those dams, the numbers are dominated by structures built for irrigation purposes (ICLD) (Fig. 2A). Furthermore, half of all large single purpose dams serve to irrigate the land (Fig. 2B). And while the purpose of dam use is more evenly distributed for multipurpose dams, still 24% of these dams are for irrigation purposes (Fig. 2C). The geographic distribution of dams is not even, as there is a lot of regional variation in the density of dams around the globe (Fig. 1A). When considering dams in the framework of Anthropogenic Biomes (or Anthromes) (Ellis and Ramankutty, 2008), the distribution is also quite variable (Fig. 3A and B). Of the dams listed in the GRaND database (Lehner et al., 2011a), there are 2095 large dams or 30.5% of the total number of large dams globally that can be found in the residential irrigated mosaic biome whereas the next highest number of dams (736 large dams or 10.7%) is found in the populated forests biome. Six of the 21 anthropogenic biomes each have $<1\%$ of the large dams worldwide within their boundaries (Fig. 3B).

Dam construction and impoundment of waterways has been carried out by humans for thousands of years for reasons that include hydropower, flood control, irrigation, water supply, navigation, and recreation among others (WCD, 2000). While it is likely that earlier dams exist, the Jawa dam in modern day Jordan is the first dam known to exist (ca. ~ 3000 BC). The dam was developed for domestic and agricultural water supply for the short-lived development of Jawa. Early dams, like the Jawa dam and the equally famous Sadd el-Kafara (ca. 2950–2750 BC) in Egypt were gravity dams where the enormous weight of the structure kept the dam in place (Fahlbusch, 2009). These early dams were built to sustain life in regions that are characterized by extreme droughts and wet periods, where dams could store rain waters during the wet periods for future use when conditions were dry. Dams that were successfully built for these purposes allowed civilization to progress. This progress resulted in better crop yields, higher survival rates, higher reproductive rates, and thus increased development. In turn, increased development resulted in greater consumption of resources and the need for advances in technology. Technological advances in dam construction continued around the globe with the Roman Empire building a plethora of dams and also the first arch dam, followed by the middle ages where dam construction showed little advancement. Beginning in the 1850s dam construction entered the modern age, as engineers began to embark on a three-dimensional understanding of the stresses on dams. Within the last 100 years the most technologically advanced dams have been built for supply water, flood control, recreation, and hydropower (White, 2016).

Dam construction in the United States saw a boom between 1950 and 1979 when there were 45,759 dams constructed (Fig. 4). The National Inventory of Dams (2019) reports that as of 2018 there are $>91,000$ dams in the United States and its territories that meet at least one of four size criteria (Fig. 1B). Just as in the global distribution of dams (Fig. 1A), the distribution of dams in the United States is also not evenly distributed (Fig. 1B). Those dams create a surface area of 18,670,124 ha and store 128,027,735 ha meters of water (National Inventory of Dams, 2019). In the U.S. alone between 500,000–600,000 miles of river (14–17% of the total river miles in the Continental U.S.) are impounded and only 312 “significant” streams are free flowing along their entirety. None of the 15 large river systems in the U.S. are free from anthropogenic impoundment (Agents of Watershed Change). Dams continue to be built around the world, largely for the production of hydropower. At the global scale there was a lull in dam construction from 1990s to 2000s, which has recently given way to a global boom. In 2014 there were 3700 major dams being constructed worldwide, each able to produce at least 1 Megawatt of power (UNEP, 2013). Through time, dams have continually gotten larger (i.e., height), yet from the 1960s to the 1980s there was a period where dam size was relatively stable, but since that period, dams have trended towards larger size (Lehner et al., 2011a,b) (Fig. 5). While records for large dams are more easily attained, the total number of dams worldwide is much more difficult to assess and is largely incomplete. Lehner et al. (2011b) estimated worldwide there to be 16.7 million dams, with reservoirs >0.01 ha.

As demand for energy around the globe continues to grow, particularly in areas such as sub-Saharan Africa and South Asia, due to increasing population and coupled economic development, a push to connect the 1.4 billion people that are disconnected from electricity supply, and continued efforts to decrease carbon emissions, the impetus to construct more dams will only continue to increase (Zarfl et al., 2015; Boyé and de Vivo, 2016). Additionally, investment in hydropower will be important as countries seek to meet their energy demands in Kyoto-compliant ways (Zarfl et al., 2015). As the world pursues the worthy goal of reducing greenhouse gas emissions, well thought out hydroelectric dams will play an important role. Along with hydropower and due mostly to human population growth and economic development, dams will continue to be seen as solutions for other water related purposes such as irrigation, development, technological change, income distribution, and life style change (WCD, 2000). As Goodland (1996) suggests, these infrastructure projects should be environmentally sound and socially equitable.

Dams and Humans

Dams have been viewed as symbols of human achievement and societal advancement as humankind has endeavored to harness natural resources for their own purposes. As such, dams have, undoubtedly, contributed to the improvement of the human condition throughout history. Water storage for irrigation, domestic, industrial, and municipal use, flood control and mitigation, and hydropower have contributed to improved human health, increased food security, created economic opportunities, and alleviated the threat of loss of life and resources. This has been particularly important in arid regions of the world (Richter et al.,

Fig. 1 (A) Global distribution of large dams based on the GRaND database. (B) Number NID listed dams within each United States county.

Fig. 2 (A) Dam purpose and single or multiple use status for large dams worldwide. (B) Percentage of use for single purpose dams worldwide. (C) Percentage of use for multipurpose dams worldwide. Source: International Commission on Large Dams (ICOLD). Available at: https://www.icold-cigb.org/GB/world_register/general_synthesis.asp (Accessed: 12 March 2019).

2010). Increasingly, dams serve multiple purposes but there is a lot of continent-to-continent variation in the function dams serve. For example, in Asia 65% of large dams function for irrigation purposes, whereas in North American only 11% of large dams serve this purpose (WCD, 2000).

If the misery of the poor be caused not by the laws of nature, but by our institutions, great is our sin.

Charles Darwin in *Voyage of the Beagle*.

While it is true that dams have had positive influences on humans, they have also had negative social and environmental impacts that tend to affect the poor, indigenous, and vulnerable groups disproportionately (Lerer and Scudder, 1999). This has largely been through the diversion of water which limits access, but construction of dams has also displaced many (WCD, 2000). For example, construction of the Three Gorges Dam in China, which produces 22,500 MW of electric power, displaced 1.2 million people (Boyé and de Vivo, 2016). Worldwide, in the 10 years between 1985 and 1995, The World Bank (1996) reported that 40 million people were involuntarily displaced by dams and a total of 40–80 million people have been displaced by dam construction (WCD, 2000). As many watersheds cross political boundaries, modification of riverine flow by dams can involve local, state, regional, and federal agencies and court battles with high stake regional environmental implications. This type of scenario is not relegated to arid regions and as an example can be seen in the “Tri-State Water Wars” of Alabama, Georgia, and Florida, USA, an area with seemingly ample rainfall and water storage but where conflict over water rights and water access arose (Tri-State Water Wars). With increased demand on water resources, coupled with the fact that nearly half of the world’s 106 primary watersheds are influenced by a major dam (WCD, 2000), cross-boundary conflicts like these are likely to increase through time and at multiple spatial scales.

Dams, particularly those that are large and used for irrigation purposes, have been found to increase the presence of vector-borne diseases (Hunter, Rey and Scotts, 1982; Lerer and Scudder, 1999) but even small impoundments have been associated with increased prevalence of vector-borne diseases (McCann et al., 2018). They have been implicated with increases in the prevalence for a variety of human health related diseases that includes encephalitis, filariasis, gastroenteritis, hemorrhagic fevers, intestinal parasites, malaria, and schistosomiasis; thereby, having important public health implications at regional or national scales (Hunter, Rey and Scotts, 1982; Lerer and Scudder, 1999; Zhu et al., 2008; McCann et al., 2018). In addition to human diseases, dams have also been found to influence animal health. For example, increases in river fluke and trypanosomiasis have been found to be associated with dam construction (Stanley et al., 2007). Dams have increased navigability, allowed for more dense human population, altered hydrological regimes and riverine ecology, and increased local agricultural practices, which has allowed vector-borne diseases to flourish (Lerer and Scudder, 1999).

Dams and Ecosystems

There is no shortage of water in the desert but exactly the right amount.

Edward Abby in Desert Solitaire: A Season in the Wilderness.

In addition to the influences dams have on human systems, dams have been shown to alter hydrologic, physicochemical, and biological systems in both the upstream and downstream direction (Katano et al., 2009; Thompson et al., 2011; Ellis and Jones,

2016; Guzy et al., 2018; Hanks and Hartman, 2018). Most studies of dam influences on ecological systems have been in general agreement with the theoretical construct of the SDC (Ward and Stanford, 1983). In fact, Stanford and Ward (2001) found only one river out of nine that they studied did not fit the SDC. Various animal taxa, including fish, aquatic macroinvertebrates, and anurans, have been shown to respond along recovery gradients below dams in a similar fashion (Ellis and Jones, 2016; Guzy et al., 2018; Hanks and Hartman, 2018) and presumably in response to altered instream and riparian habitat.

Possibly the most notable and obvious disturbance of biota by dams is that of disruption of fish migrations and specifically those of diadromous species (Petts, 1984). Of particular noteworthiness are dams that act as barriers for salmon migration in the western United States. Dams have been found to act as barriers for adult salmon swimming upstream as they return to spawn in their natal streams and juvenile salmon swimming downstream as they make their way to nursery grounds and eventually to the Pacific Ocean to mature into adults. The importance and noteworthiness of the influence of dams on salmon migration is due, in large part, to the economic value of the salmon industry. For example, in 2013 the commercial salmon industry in California alone was estimated at \$244 million U.S. dollars and the recreational salmon industry at \$105 million. The economic impact for California caught salmon was \$1176 per fish (recreational riverine salmon) and \$151 per fish (commercial ocean salmon) (Salmon economic impact: What is a fish worth?, n.d.). The Columbia River (U.S.A.) once supported vast salmon migrations to >80% of the watershed; however, due to main-stem dams, migratory habitat by 1978 had been reduced to <30% for sea-run spawning populations (Robinson, 1978).

The influence of dams on habitat (e.g., instream, riparian, and in up- and downstream directions) has been demonstrated through a variety of studies (Harvey, 1987; Katano et al., 2009; Thompson et al., 2011; Hanks and Hartman, 2018). Much emphasis has been placed on the ability of dams to disrupt sediment transport. The ability of dams to trap sediments in reservoirs has two important considerations: (1) reduction of sediment transport to downstream sections of the river and (2) loss of reservoir storage capacity due to sedimentation. The reduction of downstream sediment loads modifies sediment composition, armors stream beds, and erodes stream banks (Jones, 2010). Additionally, dams alter substrate size and velocity at sites in close proximity to dams resulting in abnormally larger substrate and higher velocities than would be expected were dams absent (Cortes et al., 2002; Poff and Hart, 2002; Katano et al., 2009; Freedman et al., 2013; Hanks and Hartman, 2018). The World Commission on Dams (2000) reports that reservoirs around the globe are losing storage capacity due to sedimentation at a rate estimated to be between 0.5% and 1% per year. This implies that without vast monetary investment in sediment removal, the reservoirs will lose 12–25% of their storage capacity every 25 years. As sedimentation fills reservoirs, their useable capacity will be reduced and there is the potential for outlet and turbine operation to be impacted, as well as increases in marshland in backwater regions (Wang et al., 2005; Zhu et al., 2008). For example, Zhang et al. (2000) predicted that within 100 years after completion of the Three Gorges Dam, 27 large-scale marshlands will emerge with a total area of 34 km². Additionally, the trapping of sedimentation in reservoirs has resulted in loss of river delta land area in places like the iconic Mississippi River Delta, where there is a >25% reduction in deltaic wetlands over the last few decades as the rate of oceanic erosion has outstripped that of sediment accretion. Sea level rise only acts to exacerbate these situations (Blum and Roberts, 2009).

In addition to the instream, longitudinal habitat modification through disrupted sediment transportation, many dams function to reduce water reaching downstream floodplains thereby decoupling an essential component of functional riverine ecosystems (Junk, Bayley and Sparks, 1989). Many rich and productive agricultural soils can be found in floodplains, where for millennia these “flood-pulses” have deposited nutrient rich sediment in river floodplains. Without this link between the aquatic and terrestrial realms, lotic system productivity is reduced and community composition and nutrient dynamics are modified (Junk et al., 1989; Bayley, 1991). The intensity of the disruption of sediment transport is variable and dependent upon the dam location and type. Run of the river dams tend to have shorter reservoir resident times and thus reduced impact on sediment transport; whereas, large dams that function for irrigation, flood-control, and hydropower typically act as effective traps for sediment (Yeager, 1993).

Riverine thermal regimes are often shifted due to dams and the magnitude of change is dependent on whether water releases are of epilimnetic or hypolimnetic origin. As aquatic species have strong phenological adaptations to water temperature (Bunn and Arthington, 2002), such disturbances can have important consequences for the timing in individuals’ life histories (Hauer and Stanford, 1982; Crowder and Magnuson, 1983; Bunn and Arthington, 2002; Williams, 2008). Waters released epilimnetically are typically well oxygenated with near ambient temperatures; however, temperatures can be elevated in the summer and winter and delay warming and cooling in downstream waters (Fraleigh, 1979). Where water is released hypolimnetically, stratified reservoirs can result in a reduction of water discharges that are 13–18 °C (TVA, 1978). Regardless of whether waters are released hypolimnetically or epilimnetically, there has been shown to be a negative impact on aquatic fauna (Yeager, 1993; Hanks and Hartman, 2018). The rate at which temperature changes as the distance from dam increases is a function of many variables (Rice et al., 2001) but the distance to recovery from thermal impacts has been found to be as much as 113 km downstream of the dam (Lehmkuhl, 1972).

Dam as Creators of Socio-Ecological Alternate Stable States

Many of the modifications described above result in long-term socio-ecological system changes and result in alternate stable states above and below dams (Bascompte et al., 2012; Collins et al., 2012; Wohl and Beckman, 2014; Skalak et al., 2017). Stable states are maintained by positive feedback mechanisms, where once the system has passed some critical point, an alternate state is imminent (Angeli, Ferrell and Sontag, 2003). Dams have the potential to break positive feedback mechanisms that maintain a stable state, whether that be in ecosystems or social systems, and the disruption of feedback mechanisms in complex systems can be the result of

abrupt external shock to the system or gradual shifts that push the system closer to a “tipping point,” where in either case, the result is a self-propagating regime shift (Bascompte et al., 2012). Skalak et al. (2017) determined that the presence of dams in the Upper Missouri River drove changes that lead to alternate geomorphic conditions and thereby resulted in an alternate stable ecological state. They concluded that this was in large part due to modified flow and sediment transport dynamics. While the findings of the Skalak et al. (2017) study that evaluated the Upper Missouri River hold true across much larger geographies, then and understanding of the global implications of modified flow and sediment transport dynamics needs a great deal of attention. As an example, Lehner et al. (2011b) found flow disruption by dams, as measured by cumulative upstream reservoir capacity that exceeds 2% of annual flow, to be greatest for large rivers (i.e., average flow >1000 m/s) where 76.7% were affected. >60% of rivers worldwide are affected by dams or diversions (WCD, 2000). While the impact dams have on flow regimes is typically considered detrimental to the riverine ecosystem, low flows, as controlled by dams, may act to restrict or prevent invasive species encroachment into stream sections upstream of dams (Acreman et al., 2009). Dams have long been agents for changing not only riverine landscapes but also social and cultural landscapes, thus resulting in a variety of socio-ecological alternate stable states. Their longevity and extent of spatial impact has enabled many dams to act as socio-ecological system modifiers, for better or worse, which has resulted in a suite of alternate stable states that have driven the transition towards anthropogenic biomes.

Dams are typically viewed as water control devices that impound lotic systems to various extents but due in large part to the difficulties of identifying small scale water control devices there are many small dams that are unaccounted for. The extent to which these small, unaccounted for dams act to modify socioecological systems is an area of research with rich questions to be asked. As an example, rice fields in the Coastal Plain of the southeastern United States and specifically along the coast of southern North Carolina, South Carolina, and Georgia have extensive dam structures that impound water at varying levels, even today (Fig. 6). South Carolina was the epicenter for rice cultivation in the southeastern U.S. and at the apogee of rice farming in the region (1860s) there was an area impounded that was approximately 60,703 ha (Ferguson, 2004). Of this vast coastal land area, Colleton County contains an estimated 20,000 ha of historic rice fields and 10 NID registered dams, yet only one dam from the NID is associated with any of these historic features (National Inventory of Dams, 2019). The vast number of dam structures (dikes) associated with these historic landscape features is unaccounted for. The interconnected, complex nature of the rice field dike systems (outer and inner dike systems) (Fig. 6C) make it difficult to account for them in dam registries such as the NID; however, ignoring a feature that has reshaped water resources across such a vast region is impertinent to their historic and contemporary impact on the socio-ecological systems within the region and the globe. Much of the impounded areas are floodplains, and while they are inundated during portions of the year, they would have been, and still are to a large extent, inundated for periods longer than they would be without these control devices.

Fig. 6 Historic rice fields in coastal South Carolina. (A) Image of a rice field dam (dike), (B) image of a rice field impoundment, and (C) areal photograph of rice fields showing in red the outer dam (dike) system, in yellow the inner dike system, and the blue polygon is the impounded rice field. Image credit: Daniel Hanks (A and B).

The enormous undertaking of creating these small impoundments was the product of the socio-economic period that was driven by slave labor and a technical knowledge system that was developed through time in western Africa. As slavery in the United States ended after the American Civil War and a new socio-economic norm developed, rice cultivation and its economic benefits also collapsed. The socio-economic-ecological system that exists within a given time frame results in a stable state that is self-correcting through a variety of positive feedback mechanisms that include social, economic, and ecological components and once one of these is broken (e.g., abolishment of slavery as a social construct) the entire system changes and may result in an alternate stable state.

Dam Removal

Records of dam removals in the United States go back to 1916 with the first recorded incident being the removal of a dam in Pennsylvania on Big Spring Run. In the United States dam removals were uncommon until the mid-1970s when environmental awareness became more mainstream and the impacts of dams were more widely known (Petts, 1984). Dam removal continued to gain momentum for the next 25 years, while dam construction saw a precipitous drop across the United States but until the year 2000, dam construction still outpaced dam removals. However, since 2000 the number of dams removed has been greater each year than the number of dams constructed (National Inventory of Dams, 2019; Duda et al., 2016) (Fig. 7). Coupled with increased knowledge of the ill effects of dams combined with continued concerns about their aging infrastructure and costs to maintain them, interest in dam removals continues to increase (Stanley and Doyle, 2003). The increased interest in dam removals has been further amplified through highly publicized dam removals such as those on the Elwha River in Washington, U.S. (Elwha and Glines Canyon Dams), which, until removed, blocked salmon migrations. Of the dams removed in the U.S. 65% have been <5 m tall and 85% have been <10 m tall. The largest dam to have been removed in the U. S. to date is the Glines Canyon Dam at 64 m tall. The Condit Dam on the White Salmon River is the next tallest dam to have been removed in the U.S. at 38 m (Duda et al., 2016).

As noted above, the negative effects of dams have been well studied and documented, yet with increased emphasis on dam removals, there has been less interest and study of the effects of dam removals. While dam removals are seen as a powerful tool to restore lotic habitats, the removal of dams can have socio-ecological impacts that should be further studied and given full consideration when dam removal is sought as a restorative measure. Ecologically, dam removal can impact downstream spawning grounds, food supply, and community composition (Sethi et al., 2004; Burdick and Hightower, 2006; Stanley et al., 2007; Orr et al., 2008). Cost-benefit analyses are often used to evaluate whether a dam should be removed but costs and benefits of socio-ecological systems (e.g., dam removal projects) are often difficult to measure, for example placing a monetary value on an endangered species and ecosystem services may be difficult in many regards as they are variable in space and time and differ among stakeholders (Daily et al., 2000; Whitelaw and Macmullen, 2006; Fisher and Turner, 2008). Regardless of these limitations, decisions by policymakers and stakeholders to remove dams are often based on cost-benefit analyses (Whitelaw and Macmullen, 2006). Whitelaw and Macmullen (2006) highlight six principles they suggest should be considered when dams are potentially being removed; however,

Fig. 7 Comparison of the number of dams constructed and the number of dams removed in the United States since 1975.

these principles are derived from an anthropocentric economic perspective and do not consider the full suite of consequences for keeping or removing a dam. As Fisher and Turner (2008) point out, there are “benefits” that extend beyond services ecosystems provide, which include recreation opportunities, aesthetics, cultural contentment, among others. All of which relate to human welfare. While extremely difficult and complicated by human interests, a full accounting of the known socio-ecological factors associated with any given dam removal project should be considered.

Glossary

Anthromes Parts of the terrestrial and aquatic biosphere considered not as pristine but as human-altered ecosystems, thereby accounting for globally significant patterns of social-ecological interaction that (re)produce these ecosystems and the various types of value they represent.

Biocultural refugia Anthromes where primary producers find refuge from pressures that are invoked by social and ecological change.

Enclosure of small-scale fisheries A process whereby small-scale fishers lose access to and control over aquatic and marine environments to industrial fishers, industries, business, or states.

Small-scale fisheries Fishing practices that are not industrialized, and which can have one or more of the following qualifications: technologically simple; low operating costs; labor-intensive; capital-extensive; different target species; artisanal; short trips; small catches; family business; diversified livelihoods; subsistence; traditional; low profitability.

Abstract

Names can be confounding. Small-scale fisheries (SSF) refer to a wide variety of fishing practices that are distinctive not only for their scale of operation. From a global perspective, small-scale fisheries include fisheries that are often (but not always) performed with artisanal gear; rely on family labor; take place in coastal environments, lakes and lagoons; and have diverse catch portfolios. In this article we investigate SSF—its characteristics and values—by considering explicitly the type of aquatic and marine environments in the Global North and South that they exploit and change. We assume that with the modernization and industrialization of fisheries these environments have acquired a more pronounced profile because SSF is becoming enclosed. To explore and discuss this assumption we use the literature on (small-scale) fisheries and our own work, and start by considering the contribution of fisheries to the transformation of aquatic and marine environments into anthromes. From here we argue that the anthromes where small-scale fishers currently operate are shrinking under the pressures from a globalizing and urbanizing world, and as such come to function as biocultural refugia. We conclude with a discussion of the implications of this trend for the overall resilience of small-scale fisheries worldwide, and the qualities and values that these types of fishery represent as alternatives to industrially organized food production that depends on growth-based economies.

Introduction

Simple gear; low operating costs; labor-intensive; capital-extensive; different target species; artisanal; short trips; small catches; family business; diversified livelihoods; subsistence; traditional; low profitability; and, of course, small. These are some of the qualifications used to demarcate small-scale fisheries (SSF) from more industrialized fishing practices (Berkes et al., 2001).

It is important to emphasize that while SSF is thought to share one essential common feature (scale), SSF practices—especially from a global perspective—are connected by several overlapping similarities, none of these common to all (Brandt, 1972; Johnson,

2006). How SSF manifests empirically is highly contingent and dependent on particular social and ecological conditions. As SSF entails such a broad variety of practices it is often complicated and problematic to make general statements about what SSF is and does.

In this article, we will investigate if the development of SSF—its characteristics and values—can be understood through the type of aquatic and marine environments in the Global North and South that they exploit and change. We assume that with the modernization and industrialization of fisheries these environments become more distinctive as anthromes because SSF is becoming enclosed. Industrial fisheries are now capable of catching fish far and deep at sea. Practices of SSF, on the other hand, are more and more limited to environments that are not suited from an economic or ecological perspective for modern fisheries. These environments might be too shallow, too difficult to navigate, or have too small stocks or species to be profitable for industrial fisheries. Such environments typically include lakes, estuaries, lagoons, wetlands, archipelagos, but even urban waterscapes. What can a focus on the shared features of the natural environments in which small-scale fishers work—lakes, lagoons, archipelagos, and coastal waters—teach us about the global characteristics, development and benefits of SSF?

To answer this question, we first conceptualize the environments that SSF exploit as anthropogenic biomes, so-called “anthromes.” The term anthrome makes explicit how human activity interacts and reproduces ecosystems. It highlights the terrestrial and aquatic biosphere not as pristine but as human-altered ecosystems, thereby accounting for globally significant patterns of social-ecological interaction that (re)produce these ecosystems and the various types of value they represent (Ellis and Ramankutty, 2008). With this definition in place we will next consider the anthromes of SSF in more detail, and argue that SSF, in the global North and South, struggle with a number of general problems, which together contribute to the enclosure of SSF. In response to enclosure, small-scale fishers worldwide face the dilemma of industrializing their business and expanding their ecological range, quit fishing, or taking refuge to marine or aquatic environments that are not particularly suited for industrialized fishing techniques. As a result of this development, the SSF that remains today is often practiced in shrinking anthromes. We conclude with a discussion of the implications of this trend for the overall resilience and sustainability of small-scale fisheries worldwide, and explore if the anthromes of SSF should be considered as “biocultural refugia” (Barthel et al., 2013), anthromes where small-scale fishers find refuge from pressures that are invoked by social and ecological change.

Anthromes in Aquatic and Marine Environments

Marine and aquatic environments have played a crucial role in human history (Fagan, 2017); its ecologies provisioned people with a varied menu of fish, sea- and water birds, shellfish, turtles, and mammals such as otters or seals. Archeological evidence points out that the earliest large and fixed human settlements around 6500 BCE sprang up in wetlands, such as the Mesopotamian alluvium. Wetlands provided people with a breadth of ecological opportunities for hunting, fishing, foraging, and gathering (Erlandson and Rick, 2010).

For a long time, it was thought that prehistoric fisheries only had a limited impact on the biology and ecology of marine and aquatic environments. Especially marine environments were considered mostly inaccessible for early fishers, and above all, inexhaustible (Roberts, 2007). But historical research has refuted the assumption that aquatic and marine environments transformed into anthromes only after the onset of fisheries industrialization (Vickers, 2004; McCauley et al., 2015). Between stone-age and fossil-fuel fisheries lies a long and varied history of innovation, acceleration and geographical expansion of fishing effort that goes hand in hand with both gradual and rapid environmental change (Pitcher and Lam, 2015; Fagan, 2017).

A telling example of the long-term environmental history of fisheries comes from Medieval Europe, where—around the year 1050—people began to include more fish in their diet. It was the urban centers with their growing populations that needed increasing bulks of protein. Fish formed a relatively easy source for this. Moreover, fish provided an important source for religious obligation (Fagan, 2008) and even prestige consumption on urban markets (Fagan, 2017). However, at the same time as urban demand for fish increased, freshwater and migratory fish stocks dwindled because stocks had problems to spawn due to the construction of numerous mills and dams, and agriculture induced siltation and sedimentation. The crisis in the freshwater fish supply in 11th and 12th century Europe made fishers turn to the sea in search of pristine stocks (Hoffmann, 2001; Fagan, 2017). A change in the urban diet followed, and people now started eating more marine instead of the freshwater and migratory fish that had traditionally been served (Roberts, 2007).

This example, along with others (see Roberts, 2007; Pitcher and Lam, 2015; Fagan, 2017), makes clear that fisheries from an early age have importantly influenced and shaped marine and aquatic environments. Some of these fisheries grew very large in terms of their manpower, financial investments, fishing capacity and geographical reach. The medieval cod and herring fisheries in Europe or the whaling industry of the 18th and 19th centuries were global, commercial fisheries that traded products over long distances. For some of these fisheries the influence was deep, long and extensive enough to transform pristine ecologies into anthromes (Roberts, 2007; Barrett, 2019).

Yet, during pre-industrial fisheries some pristine ecosystems continued to exist. These were found in inaccessible environments, such as deep offshore waters, that stayed out of human reach. Only recently these environments have turned into anthromes, when fishing boats were equipped with modern fishing technology, such as fish finders; freezers; nylon nets, and powered with steam or fossil fuel (Pitcher and Lam, 2015). Supported by these technological innovations and driven by commercial trade across the globe, fisheries quickly expanded its geographical reach to become a major global force causing irreversible changes in marine and aquatic ecological interactions (Fagan, 2017). So much so that the development of fisheries after the 1950s is documented as a sequential

depletion of stocks (Berkes et al., 2006) and trophic levels (Pauly et al., 1998) that turned aquatic and marine environments everywhere in the world into anthromes (Pitcher and Cheung, 2013).

The Creation of SSF

Although fisheries expanded its geographical reach and environmental impact since long, it was during the decades following the Second World War that fisheries development revolutionized globally through the introduction of several low-cost technological innovations, such as nylon nets (Bavinck, 2011). During these decades, a need develops especially for governments to distinguish between industrial fisheries that operate at a larger scale (e.g., larger boats, catch volumes, and longer trips) and traditional fishing practices. This is how the denotation SSF for the first time comes in use (McGoodwin, 1995). The term singles out fishers and fishing practices that somehow fail to industrialize with the purpose to target these for subsidies or loans that are supposed to enable modernization (Berkes et al., 2001).

But with the growing recognition and understanding of the environmental impact of industrial fisheries, SSF gradually gains another connotation. It becomes used to single out a type of fisheries that is believed to be relatively ecologically sustainable in comparison to industrial fishing. In this interpretation SSF has low emissions of carbon dioxide; low by-catch and discards due to the use of selective gear; high quality of the catch; low overall environmental impact on bottom sediments; and, perhaps most importantly, it is geographically bound, which means that there is an incentive to sustain fish stocks in a long-term perspective (McGoodwin, 1995). Because of these qualities SSF seems better able to meet the requirements of ecosystem-based management and post-carbon society than industrial fishing. Caution is warranted though. It is clear that SSF practices can also degrade marine environments, as exemplified with some of environmental histories of preindustrial fisheries (Vickers, 2004). Moreover, SSF practices that target a particular vulnerable key-stone species, such as eel or sharks can be ecologically unsustainable (see Björkvik et al. (2019a) for the example of eel).

Both interpretations of SSF continue to be used to justify interventions that aim to strengthen the development of rural and coastal livelihoods and communities. In the global South, the label SSF is used to signal the need for further economic development through improved technologies, access to markets, licensing, etc. (Béné et al., 2010). In the global North, it is used to suggest policies that aim to protect small-scale fishers from global economic competition (Björkvik et al., 2019a,b).

These interventions signal that SSF is under pressure in many places in the world (Kittinger et al., 2013). In the global North, its economic profitability went down; the resilience of stocks has declined due to overfishing, climate change, and pollution; and fisheries regulation has increased substantially (Björkvik et al., 2019a,b). Moreover, the competition over marine resources has intensified between SSF and protected predatory species, like seals, but also between SSF and other social groups that want to use marine environments for economic development, alternative energy production, housing, or nature recreation and conservation (Kerr et al., 2018). Small-scale fishers in the global South likewise struggle with declining resilience and productivity of marine environments due to pollution, overfishing, and climate change, and here too regulation is increasing and becoming stricter (Boonstra and Dang, 2010). Unlike in the global North, small-scale fishers in the global South also suffer from competition with other small-scale fishers, as there so many of them (Hanh and Boonstra, 2018).

Shrinking Anthromes

A number of scholars qualify these pressures as the “enclosure of the commons” (Murray et al., 2010; Pinkerton and Davis, 2015) or “ocean grabbing” (Bennett et al., 2015). Such labels highlight that small-scale fishers lose access to and control over aquatic and marine environments to industrial fishers, industries, business, or states (Bavinck et al., 2018), which consequently means that the anthromes in which SSF operates are shrinking in size. It is clear that this process impacts the development of SSF negatively, but it can also have a positive impact on aquatic and marine environments if SSF negatively impacts the resilience and sustainability of these environments. As we made clear in the foregoing, the impact of SSF on environmental sustainability is equivocal. Attention therefore needs to be paid to the social and ecological characteristics of SSF rather than assuming its practices are inherently sustainable (Björkvik et al., 2019a,b).

Small-scale fishers seek out different ways to find relief from the closure of the commons. The most straightforward response is to exit fisheries. Fishers in the global North can sometimes enable their exit through subsidies for boat scrapping or selling their fishing quotas. In the global South, this type of support is mostly non-existent, which means that many fishers have no option but to continue fishing. Exiting fisheries under these circumstances can only be done through finding alternative means and incomes to sustain livelihoods. For many fishers in the global South this means migrating to cities in search for new types of income (Hanh and Boonstra, 2018).

Another coping strategy is to expand the fishing business, through increasing the rates of return. It is important to realize that expanding fishing effort involves a qualitative change in the style of fishing. It requires considerable investments in technology to upgrade vessels and gear, perhaps to buy fishing quota and/or licenses, but also a willingness and capacity to take risk with investments and to expand fishing beyond the local environments to target new and larger fishing grounds.

Some small-scale fishers can or are not prepared to make such changes. This group applies a number of strategies to remain fishing but without scaling up their businesses (Salmi, 2015; Boonstra et al., 2018). A first strategy is to reduce operation costs

by maximizing use of local social and natural capital (Boonstra and Hentati-Sundberg, 2016). Examples include reliance on family labor, non-monetized economic exchange, repairing rather than replacing gear and vessels, and using own skills and knowledge or from family/friends to do repairs. A second strategy is to diversify fishing livelihoods. Diversification can relate to the fishing practice itself, when fishers target a broad spectrum of species, e.g., freshwater and marine species, but it also relates to their livelihoods when they obtain income from various other activities, which can include farming, trading, or manual labor (Allison and Ellis, 2001; Salmi, 2005). A third strategy is to innovate small-scale fisheries by gearing it to (urban) markets for local and niche food. Examples here include the selling of local fish through fisher-owned shops and restaurants, but also the marketing and processing of fish as an exclusive product (Björkvik et al., 2019a,b). Below we present two vignettes of SSF in the global North and South which illustrate various ways in which fishers cope with the enclosure of the commons, but also the continuous development of SSF.

Vignette From the Global South: The Tam Giang Lagoon

The Tam Giang Lagoon is located in Thua Thien Hue province, in the centre of Vietnam. With an area of 20,000 ha and length of 70 km, it is the largest lagoon in the Southeast Asia. The lagoon is a brackish water ecosystem with rich biodiversity and biomass and provides livelihoods for 100,000 people via small-scale fishing and aquaculture (Hanh and Boonstra, 2018).

Fishing is a traditional livelihood activity and performed with stationary fishing gear fixed in certain places in the lagoon, e.g., stake traps and bottom nets, and mobile fishing gear that is moved around in the lagoon, e.g., gillnets and steel-framed bottom traps. Although fisheries in the lagoon has been targeted since the 1950s/1960s it continues to operate under a de facto open access regime (van Tuyen et al., 2010). Since the 1980s fishing effort increased, because regulation was not able to pose limits on fishing effort, while so-called Doi Moi policies ("renovation" policies) connected Vietnam to global markets, which promoted seafood exports pushing the price of seafood upwards. Moreover, population in the lagoon grew and improved fishing technology, such as nylon nets but also electric fishing gears and steel-framed traps, became available and affordable (Boonstra and Nhung, 2012). As a result, the number of fishers in the lagoon rose dramatically between 1982 and 1993 from 5575 to 9120. The total fish catch of the lagoon also spiked from 850 ton in 1976 to 2112 ton in 1993. Yet, fish catch per household decreased steadily since the early 1990s (Ho et al., 2016).

By the early 1990s, aquaculture was introduced to the lagoon and expanded rapidly (Boonstra and Nhung, 2012). The Vietnamese government helped to support the establishment of aquaculture through provisioning loans against low interests and giving out areas in the lagoon for tenure. With this support and the high international and national demand for seafood the area in the lagoon used for aquaculture increased from 20 ha in 1990 to 4200 ha in 2006 and developed into an intensive monoculture (Boonstra and Hanh, 2014). The introduction and development of aquaculture deteriorated the lagoon water quality dramatically as it increased waste loads, which contributed to eutrophication, and high levels of coliform density and organochlorine pesticides (van Tuyen et al., 2010). This deterioration in turn impacted the growth and health of aquatic and marine species. Moreover, the expansion of aquaculture through the lagoon also reduced and contaminated nursery and spawning areas as well the fishing grounds for small-scale fishers (Armitage and Marschke, 2013).

As a result, small-scale fishers in the lagoon have been struggling to keep catches sufficiently high (Hanh and Boonstra, 2018). They do so primarily by increasing their exploitation efforts as they lack the capacity and alternative opportunities to earn income outside fisheries (Armitage and Marschke, 2013; Hanh and Boonstra, 2019). It goes without saying that this response only accelerates a deterioration of the lagoon resources and thus in the long run local fishers' livelihood.

Since the middle of the 2000s, alarmed by the deteriorating sustainability of the lagoon, the provincial government has implemented a number of measures to improve the lagoon resources as well as the users' livelihoods (Armitage et al., 2011). Fisheries regulation has been enforced more stringently, and several types of gear are now prohibited, while other more artisanal, benign types are encouraged to be reused, such as bamboo traps. The government also started allocating territorial user rights for fisheries to user groups as a way to limit access and improve the monitoring and enforcement of fisheries regulation. The construction of new aquaculture ponds is prohibited, and existing ponds are encouraged to contain more extensive polycultures to minimize waste load and the spread of diseases (Hanh and Boonstra, 2018). Moreover, the government installed 26 nursery and spawning areas (equivalent to 2.8% of the lagoon area) to improve species reproduction and survivals. In addition, the lagoon now houses 400 artificial reefs where a total of 400,000 juvenile fish, shrimp and crab are introduced. Finally, the reduced catches from the lagoon are of much less interest to global markets where buyers want to purchase large quantities. As a result, fishers and aquaculturists in the lagoon are nowadays returning to supplying local markets with freshly caught fish.

Vignette From the Global North: The Stockholm Archipelago

The Stockholm archipelago is the second largest archipelago in the Baltic Sea, consisting of over 24,000 islands. It covers an area of 1700 km² from Vaddö island in the North to Öja island in the South around 150 km, and extends from Stockholm city 80 km eastward (Hedenstierna, 1989).

Fisheries has been a primary livelihood activity for the inhabitants of the archipelago for many centuries. It used to be one of the activities that local peasant communities engaged in, next to farming and forestry (Thornström, 1978; Löfgren, 1979; Selling, 2010). This peasant lifestyle disappeared after the Second World War with the introduction of new catch methods, such as pound nets for

catching eel introduced in the 1960s, and the demand for work in urban centres (Selling and Holmer, 2007; Björkvik et al., 2019a,b), such as Stockholm City. From then onwards the style of fishers in the archipelago became more distinct as a small-scale operation because it differed considerably from other fisheries that industrialized and expanded their operations financially and geographically (Boonstra and Hentati-Sundberg, 2016).

The remaining professional fisheries in the Stockholm archipelago is predominantly a mixed-species fishery that targets cod, herring, flounder, eel, whitefish, perch, pike and pikeperch. Fishers own boats that are often smaller than 12 m, and combine a number of gear types, including mostly traps and gillnets. Since the 1970s most of the fishers in the archipelago stopped or retired. At the moment, there are approximately 30 professional fishers left (Andersson and Sjöberg, 2012).

A number of changes has made it more difficult to provide oneself a livelihood based on fishery in the archipelago. The economic profitability of the fishery has been in decline the recent decades (Waldo et al., 2013). At the same time, the resilience of Baltic fish stocks is impaired due to overfishing, climate change, and eutrophication (Blenckner et al., 2015). As a consequence of these changes fisheries regulation has increased substantially (Hentati-Sundberg and Hjelm, 2014). Moreover, fishers also face increased competition over fish and marine resources from growing seal and cormorant populations (Königson, 2011) as well as other stakeholders that aim to use the archipelago for economic or leisure purposes.

Historically, fishing used to be a very important livelihood strategy in Stockholm innercity as well (Ericson Wolke, 2001). With its currents, its brackish and sweet water Stockholm offered lots of opportunities for catching a wide variety of fish. It currently still has around 30 different species, making the city one of the most species-rich fishing locations in Sweden (Stockholm City, 2019). The most common way of fishing in the Stockholm inner city has traditionally been seine fishing and fishing with hand nets. This way of professional small-scale fishing disappeared during the second half of the 20th century (Ericson Wolke, 2001).

With industrialization and modernisation, the character and role of fishing in Stockholm City changed. Industry and untreated sewage discharge deteriorated the health of the water and the health of the fish stocks. Moreover, with the development of modern trade and retail, city folk increasingly purchased fish from elsewhere in supermarkets supplied by global production networks. In fact, it has become difficult nowadays to find and purchase fish from the region in Stockholm (Andersson and Sjöberg, 2012). Yet, fishing in the city never completely ceased. The efforts for the improvement of the water quality towards the end of the 20th century (Ericson Wolke, 2001), and the yearly release of around 35,000 salmon and trout in the inner-city, maintain a fishing stock that currently attracts a culturally diverse group of anglers. In a remarkable contrast with professional fisheries in the wider archipelago, fishing in Stockholm's innercity has recently reinvigorated after a long time of decline. Some of these fishers fish purely for recreation using catch and release, but there are also others who fish in the city for providing themselves and others with food. In any case, it seems that the (mostly) free access and improved ecologies of urban waters in Stockholm City has reinvigorated a small-scale fishery that provides a culturally and economically diverse group of urban dwellers with opportunities for leisure and food.

Discussion: From Anthrome to Refugium?

As exemplified in the two vignettes, small-scale fishers globally are pressured from various social and ecological changes, which include the deterioration of aquatic and marine natural resources as well as intensified economic competition and stricter government regulations. For many small-scale fishers worldwide it is becoming increasingly difficult to maintain their business and livelihood (but there are of course exceptions, i.e., places where small-scale fishers are doing well, see e.g., Boonstra et al., 2018 for the example of the vendace fishery in Northern Sweden).

Despite global differences small-scale fishers generally are losing access to and control over aquatic and marine environments. As a consequence, they are becoming more dependent on environments that, for various reasons, are not targeted by industrial fisheries, other businesses or governments. Sometimes, small-scale fishers are forced to operate in these areas due to government restrictions or exploitation of marine and aquatic environments by other economic actors. In other cases, small-scale fishers might choose themselves to focus on and operate in these environments because it enables them to avoid competition with more powerful actors, or to access a niche market (based on a certain species or locality) from which to improve profits.

What unites these environments is that they currently lie outside of the interest of industrial fishers or other larger-scale economic businesses operating in the marine and aquatic economy. They can be economically unattractive for a number of reasons: the environments may be inaccessible for industrial fishers, e.g., too shallow and therefore only allowing small vessels (Murawski, 2000); they may be habitats for fish that are not in high demand on the markets the industrial fishers target; or they may not allow a uniform catch in terms of volume and species composition because of seasonal variability and/or species, thus complicating a constant and large market supply (Johnson et al., 2005).

We suggest that the marine and aquatic environments that continue to allow the establishment and sustenance of SSF can be defined and further explored as a specific anthrome, namely an anthrome that is shrinking due to the further enclosure of marine and aquatic commons under the pressure of competition over access to and control over natural resources. Can such shrinking anthromes of SSF be characterized and understood as biocultural refugia? Biocultural refugia accommodate small-scale fisheries that represent various forms of capitals that otherwise would be outcompeted and made redundant.

As we demonstrated with the enclosure of SSF, and the two vignettes, SSF in the global North and South are currently undergoing major changes. With ongoing urbanization and globalization many small-scale fisher livelihoods are discontinued. The small-scale fishers that continue their businesses often have to compete with a growing interest in aquatic and marine environments coming from corporations, environmental conservation, or states. Under these pressures small-scale fishers are seeking out places and

species that are relatively underexploited and/or which exploitation can only accommodate a knowledge and labor-intense operation. Surely not all SSF can be characterized in this way, but we expect that in the future the remaining small-scale fishers will find refuge in anthromes that have these characteristics.

As such these refugia maintain working alternatives to industrially organized food production that is inherently tied to economies that are based on continuous growth of output (Roelvink et al., 2015). From a resilience perspective, the existence of biocultural refugia that enable small-scale fisheries represents a valuable resource because they contribute to response diversity needed for transitions towards more sustainable societies (Boonstra and Joosse, 2013).

At the same time as the anthromes of SSF are shrinking, we also perceive the (re)establishment of anthromes especially in urban settings. As the vignette of Stockholm city illustrates, SSF in different forms may return as soon as new opportunities develop. The presence, development and (re)establishment of fisheries in urban waters in both the global North and South is currently an undervalued and forgotten manifestation of SSF. We foresee that the importance of urban SSF will continue to grow in a quickly urbanizing planet and therefore demands (scientific) attention and management.

The example of urban SSF also nicely illustrates the unique polymorphous nature of SSF stemming from the ability of small-scale fishers to respond differently to changing circumstances through improvisation and make-do with the resources at hand (Baker and Nelson, 2005). A characteristic that also makes capturing SSF—its qualities and benefits - in generic or quintessential definitions impossible and perhaps not useful. Based on the analysis offered here, we argue that SSF can be understood and valued as highly diverse practices that can offer alternatives to industrialized, monetized and expansive fisheries. But, the social and ecological benefits and opportunities of its various local manifestations need to be assessed time and again, because SSF is inherently variable and diverse.

Moreover, the existence of refugia for SSF, and the resilience of small-scale fishers, does in itself not guarantee the preservation of knowledge and skill important for a transition to sustainable exploitation of marine and aquatic resources. Several challenges continue to threaten the livelihoods of small-scale fishers. One challenge is generic regulations that fail to distinguish between different types of fisheries. Previous studies have shown that regulations often disfavor SSF because they impede the maintenance of a diversified fishing (Hentati-Sundberg et al., 2015). Another challenge is the lack of recruitment and succession of young fishers. There are few examples of new entrants into SSF, and the number of sons and daughters continuing their family's small-scale fishing operation is decreasing, among others because the economic pay-off from small-scale fishing is low (Blomqvist et al., 2016). A final challenge concerns changes that are induced from global inter- and teleconnections (Hull and Liu, 2018) from which even refugia are not exempt. Indeed, research indicates that the health and size of local fish stocks is impacted by activities that take place in far-removed locations (Drouineau et al., 2018), such as off-shore fishing (Sumaila et al., 2015), or pollution from industry.

Conclusion

In the late Anthropocene fishers started to power their boats with fossil fuels and adopted technologies that allowed them to scale up their fishing range and effort. The fishers that lagged behind this development, either by choice or from necessity, are nowadays known as small-scale fishers. Defined originally foremost by what they were not, namely industrialized and modernized SSF, houses a great number of different fishing styles whose diversity is impossible to cover in a quintessential definition.

Despite the tremendous global diversity of this type of fisheries, there are a number of common threats to their existence and development. Based on an overview of these threats, and our knowledge of their specific and local manifestation in the global North and South, we have argued that the anthromes that continue to host SSF could be characterized as biocultural refugia. These refugia represent valuable storehouses of knowledge and skills that have potential to contribute to post-growth societies that use and preserve aquatic and marine environments sustainably.

To be sure, we are not suggesting in this article to turn back the clock, but rather to utilize the unique skill and capabilities of small-scale fishers to enable a transition to a post-growth and renewable energy use of aquatic and marine environments. Such a transition would involve the retro-innovation (Stuiver, 2006) rather than re-establishment of SSF to benefit sustainable development.

Abstract

Environmental contaminants known as endocrine disruptors (or endocrine-disrupting chemicals, EDCs) are increasingly detected in marine systems. EDCs are structurally diverse compounds including steroids, phenols, phthalates, organochlorines, and organotins; these compounds are found in pharmaceuticals, pesticides, personal care products, plastics, and a variety of other products. EDCs in the marine environment wind up in the water column, in organisms, and adsorbed to sediments, especially in the shallow neritic zone and in bodies of water that experience limited water exchange. The fate of marine EDCs is determined by a combination of abiotic and biotic processes. Some EDCs are susceptible to degradation but are nonetheless perpetually present in marine systems due to continuous replenishment and are therefore considered pseudo-persistent. Others are remarkably stable and resist degradation and thus are considered persistent. Persistent EDCs are often lipophilic and thus tend to bioaccumulate and biomagnify. EDCs interact with the endocrine systems of animals by interfering with the concentrations or activities of hormones or their receptors, thereby leading to reproductive, developmental, metabolic, or behavioral dysfunction. Many EDCs agonize or antagonize hormone receptors, while others modulate the activities of enzymes involved in synthesis or metabolism of hormones or alter the expression of genes that encode receptors or protein hormones. Much has been learned in the last several decades about the presence of EDCs in marine systems and the effects of EDCs on some marine organisms. However, existing knowledge gaps must be addressed if we are to understand the scope of human impacts on marine systems. In addition, priority must be given to developing remediation strategies that both reduce the inputs of anthropogenic EDCs into marine systems and mitigate the effects of these chemicals in marine organisms.

Introduction to Endocrine Disruptors

Many human impacts on coastal and marine ecosystems are obvious and well documented; these impacts include habitat alteration or destruction, introduction of invasive species, extinction of native species, overfishing, and pollution. Other human impacts are not as well recognized though certainly no less troubling. For example, environmental contaminants known as endocrine disruptors (or endocrine-disrupting chemicals, EDCs) are increasingly detected in coastal and marine systems. An EDC is defined by the US EPA as “an exogenous agent that interferes with the production, release, transport, metabolism, binding, action or elimination of natural hormones in the body responsible for the maintenance of homeostasis and the regulation of developmental processes” (Kavlock et al., 1996). EDCs are structurally diverse compounds that can be found in pharmaceuticals, pesticides, personal care products, plastics, and a variety of other commercial and industrial products. These compounds interact with the endocrine systems of animals by mimicking, blocking, or altering the metabolism of hormones or their receptors, leading to reproductive, developmental, metabolic, or behavioral dysfunction. The most well studied hormones that are susceptible to disruption by EDCs include sex steroids (e.g., estrogens, androgens, or progestins), thyroid hormones, protein hormones (e.g., gonadotropins and glucoregulatory hormones such as insulin and growth hormone), and molting hormones, though other signaling pathways (e.g., those involving nitric oxide, heat shock proteins, and immune mediators) are also susceptible. While many natural compounds (such as phytosterols and pheromones) can be considered EDCs, this article focuses on anthropogenic EDCs as they relate to human impacts in estuarine and marine systems.

Sources and Fates of Endocrine Disruptors in the Marine Environment

Anthropogenic EDCs are produced and primarily used in terrestrial systems, but they readily enter the aquatic environment by way of sewage or wastewater effluent, landfill leaching, industrial discharge, and surface water runoff from urban and agricultural areas.

EDCs in ground and surface waters eventually make their way to the ocean. EDCs can also enter the marine environment directly from mariculture facilities and marine vessels. Regardless of source, EDCs in the marine environment wind up in the water column, in organisms, and adsorbed to sediments.

The ultimate fate of a marine EDC is determined by a combination of abiotic processes such as photolysis, hydrolysis, volatilization, ionization, and sediment sorption as well as biotic processes such as absorption, metabolism (or biotransformation), and elimination. Within organisms, metabolism of EDCs occurs via one or both of two phases. In phase I metabolism, xenobiotics including EDCs are oxidized, reduced, or hydrolyzed, typically by enzymes in the cytochrome P-450 (CYP) protein family. In phase II metabolism, xenobiotics are converted into more hydrophilic metabolites, which are easier to excrete, via the conjugation of polar functional groups including glucuronic acid, sulfate, glutathione, and acetyl groups. Aspects of water chemistry, such as pH and osmolarity as well as temperature, also dictate the fate of marine EDCs, as these factors can affect solubility as well as rates of degradation and uptake. Some EDCs, including many pharmaceutical compounds, are susceptible to abiotic and biotic degradation but are nonetheless perpetually present in marine systems due to continuous replenishment (e.g., via wastewater inputs) and are therefore known as *pseudo-persistent organic pollutants*. Others, notably the very stable organochlorine compounds such as polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethane (DDT), resist biotic and abiotic degradation and thus are known as *persistent organic pollutants* (POPs).

The stability of POPs such as PCBs and DDT allows them to accumulate for long periods of time, thereby increasing the chance that their concentrations in the marine environment will reach or exceed observable adverse effect levels. The persistence of POPs also allows them to remain intact through repeated cycles of vaporization and condensation. On a global scale, the process by which such chemicals vaporize, travel via air currents to cooler locations, and then condense is known as global distillation (or *the grasshopper effect*). Over the course of many years, global distillation slowly transports POPs from warmer to cooler locations and thus from lower to higher latitudes and altitudes, causing POPs to accumulate on mountaintops and around the poles (Fig. 1; Wania and Mackay, 1996). In this way, the regions of the globe farthest from human industry and agriculture are becoming some of the most contaminated with POPs, many of which are EDCs.

Fig. 1 Mechanisms responsible for the migration of chemicals around the globe. In the tropics, the rate of evaporation exceeds the rate of condensation or deposition; at the poles, the opposite is true. The process by which stable, persistent organic pollutants (POPs) vaporize, travel via air currents to cooler locations, and then condense is known as global distillation (or “grasshopping”). Over the course of many years, global distillation transports POPs from warmer to cooler locations and thus from lower to higher latitudes and altitudes, causing POPs to accumulate on mountaintops and around the poles. Figure reprinted with permission from Wania F and Mackay D (1996) Tracking the distribution of persistent organic pollutants. *Environmental Science and Technology* 30: A390–A396.

The majority of POPs are problematic not only because they can act as EDCs and disrupt hormonal pathways in animals but also because they are lipophilic (or “fat-loving”). Lipophilic chemicals readily distribute into fatty tissues such as brain and adipose tissue, from which they can be remobilized during periods of weight loss. This remobilization process liberates POPs from fat stores in lactating mammals, such that males often have higher total body burdens of POPs compared to females in their reproductive years. However, this pattern comes at a hefty cost, as POPs liberated from maternal fat stores are directly transferred to neonates via milk. POPs also tend to bioaccumulate and biomagnify due to their lipophilic properties. For this reason, the concentration of POPs measured in marine primary producers (e.g., algae) exceeds that of the water (due to bioaccumulation), and the concentration measured in consumers often exceeds that of producers (due to biomagnification). Top predators including large, migratory fish and marine mammals may be especially vulnerable to the effects of POPs given their terminal positions in the food web. For example, organochlorine levels in top predators like odontocetes (e.g., striped dolphins and beluga whales) can be an order of magnitude higher than in planktivores such as mysticetes (e.g., fin whales; [Fossi et al., 2003](#)). Terminal predators that live near the poles experience the combined effects of biomagnification and global distillation, causing animals such as polar bears, seals, and whales (as well as the indigenous humans who consume them) to have incredibly high body burdens of these toxic chemicals.

Concentrations of EDCs in estuarine and marine systems also depend heavily on hydrodynamics. For instance, EDCs tend to be more concentrated in the neritic zone, which overlies the continental shelf and is located near the coastline, than in the deeper oceanic zone. This pattern is likely explained by higher rates of dispersion and dilution that occur in offshore, oceanic environments than in shallower, nearshore areas. Not surprisingly, concentrations of EDCs are especially high in shallow coastal waters near major human population centers. Estuaries, which are important nursery grounds for many coastal organisms, are particularly vulnerable to EDC contamination, especially when agricultural run-off or effluent from sewage or wastewater treatment plants or from other industrial activities enters upstream waters. As rivers drain into estuaries and water velocity slows, particulate matter settles in a process known as sedimentation. Organic matter in sediments acts as a sorbent for nonpolar (i.e., lipophilic) compounds, whereas minerals in sediments act as a sorbent for polar and amphiphilic compounds. Contaminants bound to particulate matter thereby concentrate in estuarine sediments. For this reason, demersal (or bottom-feeding) estuarine animals that consume benthic prey often demonstrate higher contaminant loads than animals that feed higher in the water column. Sediment-bound contaminants can be liberated by flood tides, dredging, or other processes that disturb the estuary floor, such that concentrations of EDCs vary both spatially and temporally.

Marine contaminants such as EDCs also tend to accumulate in water bodies that experience limited water exchange. For example, organisms in the Mediterranean Sea often demonstrate contaminant loads an order of magnitude (or more) greater than those measured in Atlantic or Pacific organisms ([Aguilar et al., 2002](#)) due to the fact that the Mediterranean is surrounded by some of the most populous countries in the world and experiences only minimal exchange with the Atlantic Ocean. The Baltic Sea also participates in limited exchange with the North Sea and thus accumulates contaminants originating from industrial operations in the Rhine River basin.

Hydrodynamics also determine the fate of marine litter plastics and microplastics, which contain endocrine-disrupting additives like alkylphenols, plasticizers like alkyl or aryl esters of 1,2-benzene-dicarboxylic acid (also known as phthalates), monomers like bisphenol A (BPA), and stabilizers like tributyltin (TBT). The world's oceans receive plastic particles of various sizes at a rate of approximately 8 million metric tons per year, the majority of which end up on the sea floor ([Gallo et al., 2018](#)). Plastics also accumulate in floating patches in all five of the world's major ocean gyres, in bodies of water with limited exchange, and in polar areas. Plastics of all sizes can serve as both sources of and sinks for marine EDCs, as contaminants can both leach out of and adsorb into the pores within plastics. Migration of chemicals out of plastics is highest for small additives leaching out of polymer matrices with large pores. Typically, the chemicals that leach out of plastics are unreacted components left over from the manufacturing process, as these components are not covalently bonded to the polymer matrix. In addition, lower molecular weight compounds such as dimethyl phthalate and alkylphenols with short alkyl chains are more water-soluble and thus leach out of plastics more quickly than higher molecular weight compounds like di-2-ethylhexyl phthalate and alkylphenols with long alkyl chains. While plastics leach EDCs into marine systems, they can also concentrate other organic contaminants because of their lipophilic (i.e., hydrophobic) properties. Polyethylene plastics have a particularly high affinity for hydrophobic compounds and therefore sorb and concentrate more organic contaminants than other plastics such as polyvinylchloride (PVC) and polypropylene. Contaminants adsorbed onto marine plastics can travel long distances, protected from degradation by encapsulation within the matrix of plastic polymers. Aided by low temperatures, high salinity, and low light conditions, this molecular encapsulation increases the half-lives of adsorbed contaminants and thereby contributes to their pseudo-persistence in marine environments.

Effects of Exposure to Endocrine Disruptors in Marine Organisms

EDCs can be taken up into marine organisms by absorption across the skin or gills, inhalation, or ingestion. Given that most EDCs are at least moderately lipophilic, they are often readily absorbed across epithelial membranes (e.g., in the skin, gills, or lungs) into body fluids by simple diffusion. In the special case of contaminant-laden plastics, EDCs can be transferred out of the plastics and into organisms after ingestion of either plastic particles, which are often mistaken for food, or prey items that previously consumed plastics. Within the digestive tract, where organic materials and natural surfactants such as amphiphilic bile salts accumulate, contaminants may be especially likely to desorb from plastics into digestive fluid, from which they can be absorbed into body fluids. Once absorbed into circulation, EDCs can then exert a variety of effects on development, reproduction, and homeostasis. Unlike

typical toxicants, for which the magnitude of detrimental endpoints often demonstrates a linear or exponential relationship with dose, many EDCs are associated with nonmonotonic (i.e., U-shaped or inverted U-shaped) dose-response curves. EDCs are especially problematic because they are bioactive at extremely low doses (on the order of ng L^{-1}), which often correspond to environmentally relevant concentrations. In addition, many EDCs exhibit trans-generational effects that are mediated by epigenetic responses to exposure, such that the impacts are experienced one or more generations after exposure.

The pathways associated with steroid hormones, including estrogens and androgens, are major targets of EDCs. When exposure to EDCs is associated with responses similar to those induced by endogenous estrogens or androgens, those EDCs are said to have *estrogenic* or *androgenic* effects, respectively. Conversely, when EDCs inhibit the activity of endogenous estrogens or androgens, those EDCs are said to have *anti-estrogenic* or *anti-androgenic* effects, respectively. The majority of EDCs elicit such effects either by binding to the extracellular face of membrane-bound receptors or by diffusing across cell membranes and binding to intracellular receptors located in the cytoplasm or nucleus. Chemicals that bind to receptors and activate them are known as *agonists*, whereas chemicals that bind to receptors and inactivate them are known as *antagonists*. Many EDCs are either agonists or antagonists of hormone receptors such as estrogen or androgen receptors. The estrogen receptor in particular is implicated in responses to a number of EDCs, as this receptor is notoriously “promiscuous,” meaning that it demonstrates an affinity for a variety of compounds other than its endogenous ligands (estradiol, estrone, and estriol). Natural and synthetic compounds found in the environment that are able to agonize the estrogen receptor are collectively termed *environmental estrogens* or *xenoestrogens*.

Other EDCs stimulate or inhibit enzymes involved in synthesis, metabolism, or excretion of hormones or their receptors. For example, several known EDCs modulate the activity of CYP enzymes involved in steroid synthesis and phase I metabolism or conjugating enzymes involved in phase II metabolism, thereby altering the production of endogenous hormones or the clearance of both hormones and xenobiotics. Still other EDCs alter the expression of genes that encode hormone receptors or protein hormones. The mechanisms by which several classes of the better studied EDCs exert their effects are described below.

Pharmaceutical Estrogens

Pharmaceuticals constitute approximately a quarter of global chemical production (Murmans, 2003) and are used worldwide for both medicinal and agricultural purposes. Pharmaceuticals with substantial endocrine-disrupting capabilities include steroidal estrogens such as estrone (E1), 17β -estradiol (E2), and estriol (E3) as well as 17α -ethinylestradiol (EE2), the synthetic estrogen commonly found in birth control pills. Municipal sewage treatment plants do not remove or degrade most pharmaceutical compounds, so medications (including steroids) that are discarded or excreted into sewer systems are released unchanged into the environment by way of sewage treatment plant effluent. Steroidal estrogens are also used in high density livestock production facilities and thus are found in higher levels in marine systems impacted by agricultural runoff. Steroidal estrogens have been detected in marine systems globally, but their concentrations are often higher in estuaries than in the open ocean. Estuarine sediments in particular seem to be a sink for steroidal estrogens.

In vertebrate animals, natural and synthetic steroidal estrogens bind to and agonize both intracellular and membrane-bound estrogen receptors. Vertebrates express two isoforms of intracellular estrogen receptors (ESRs), termed estrogen receptor 1 (ESR1, formerly ER α) and estrogen receptor 2 (ESR2, formerly ER β). Due to a teleost-specific whole genome duplication, teleost fish express two versions of ESR2 (ESR2a and ESR2b). Upon activation by steroidal estrogens, ESRs dimerize and function as transcription factors, thereby regulating expression of estrogen-sensitive genes. Membrane-bound (or G protein-linked) estrogen receptors (GPERs) also bind steroidal estrogens, although the pathway downstream of ligand binding differs from the pathway involved in ESR signaling.

Exposure to steroidal estrogens at inappropriate concentrations or during inappropriate developmental windows alters gene expression and is associated with a variety of effects in vertebrates including feminization of males. For example, males of oviparous (or egg-laying) fish species that are exposed to exogenous estrogens often express vitellogenin, a female-specific protein produced in response to estrogens by the liver for subsequent incorporation into yolk. Exposed male fish also commonly develop ovotestes, or male gonads containing oocytes (or eggs), and they suffer impaired spermatogenesis, decreased sperm motility, and decreased sperm counts. In both male and female fish, exposure to exogenous steroidal estrogens leads to additional detrimental outcomes such as decreased fertility, increased incidence of certain cancers, and increased mortality. Invertebrates are also affected by exogenous steroidal estrogens, which are associated with developmental delays and female-biased sex ratios in marine invertebrates such as polychaete worms, molluscs, and crustaceans (Forget-Leray et al., 2005; García-Alonso et al., 2011; Ruiz-Velázquez et al., 2018).

Phenols

Phenols are aromatic organic compounds that consist of a phenyl group covalently bonded to a hydroxyl (or alcohol) group (collectively called a phenol group). The most common phenols in the marine environment include bisphenols like bisphenol A (BPA), which contains two phenols connected by an alkyl group, as well as alkylphenols (APs) and their derivatives, alkylphenol ethoxylates (APEOs), which both contain a phenol group covalently joined to an alkyl chain. BPA and its relative, bisphenol S (BPS), are used in the production of polycarbonate plastics, which can be found in food and beverage containers, electronic devices, plastic lenses, and automotive products. Bisphenols are also components of epoxy resins that are used in thermal paper and as linings of

food and beverage containers as well as water pipes. APs and APEOs are used as surfactants, detergents, emulsifiers, dispersants, and stabilizers in products such as paints, adhesives, lubricants, phenolic resins, fire retardants, pesticides, textiles, personal care products (including fragrances), and a variety of plastic goods.

The primary inputs of phenols into marine systems occur by way of sewage and wastewater treatment plant effluent and industrial discharge. Thus, marine phenols reach their highest concentrations in coastal areas near human population centers. Because BPA, BPS, and APs are used as building blocks in a variety of plastic goods, marine litter plastics can also leach phenols into seawater directly, though APs with longer alkyl chains are less likely to leach than APs with shorter alkyl chains (Teuten et al., 2009). Microbes residing in shallow sediments transform less toxic APEOs into more toxic APs including nonylphenol (NP) and octylphenol (OP). The length of alkyl chains determines the rate of transformation of APEOs into APs, as APEOs with long alkyl chains resist degradation and therefore persist in the environment for longer periods of time than APEOs with short alkyl chains (David et al., 2009).

Although APEOs are not typically considered EDCs, APs as well as BPA and BPS are estrogenic, meaning that they bind to and agonize ESRs (and are thus considered environmental estrogens). In addition, APs are also anti-androgenic, meaning that they bind to and antagonize androgen receptors (Bonefeld-Jørgensen et al., 2007). Thus, as with steroidal estrogens, exposure to bisphenols and APs is associated with feminization in males and resulting decreased fertility. Also like steroidal estrogens, phenols associate with particulate matter and are found at their highest concentrations in sediments of coastal areas including estuaries, lagoons, and harbors. Because phenols are amphiphilic, they can adsorb to both sorbent organic matter and minerals in sediments. As a result, bottom feeders and sediment-dwelling organisms (including demersal filter feeders) accumulate higher concentrations of phenols than marine organisms that live higher in the water column (David et al., 2009).

Plasticizers

Plasticizers are additives used in the production of plastics to reduce the attraction between polymer chains, thereby increasing the flexibility and durability of the resulting plastic. The most common plasticizers are phthalate esters, which are used primarily in the manufacturing of products made from PVC, including shower curtains, upholstery, flooring, and food containers. Phthalates are also used as dispersants, binders, and emulsifiers in personal care products, adhesives, detergents, paints, and pharmaceuticals. When used as plasticizers, phthalates are not covalently bonded to the polymer matrix and thus readily leach from plastics, especially when the plastics are exposed to elevated temperatures, low pH, or ultraviolet light. Lower molecular weight phthalates such as dimethylphthalate (DMP) are less hydrophobic and thus leach more readily from plastics than higher molecular weight phthalates like diethylhexylphthalate (DEHP). Landfill leachate and marine plastic litter, along with industrial discharge, are the primary sources of marine phthalates. For this reason, marine phthalates, like phenols, reach their highest concentrations in coastal environments near human population centers.

Unlike pharmaceutical estrogens and phenols, phthalates are anti-androgenic (Grady and Sathyanarayana, 2012), meaning that they interfere with the activity of androgens such as testosterone and dihydrotestosterone. Specifically, phthalates inhibit enzymes involved in steroidogenesis, thereby decreasing circulating levels of androgens. Exposure to phthalates is associated with a number of detrimental effects in male vertebrates, including malformations of the reproductive tract, decreased phallus size, impaired sperm production, and decreased sperm count. In essence, exposure to phthalates during the period of sex determination causes demasculinization (or feminization) of developing male vertebrate animals.

Organochlorines

Organochlorines (OCs) are organic compounds that contain at least one covalently bonded chlorine atom. Synthetic OCs include a number of EDCs such as polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethane (DDT) along with its metabolites (especially dichlorodiphenyldichloroethylene or DDE). Although the use of many OCs has been outlawed or restricted in most countries for several decades, OCs are generally stable molecules that bioaccumulate within organisms and biomagnify through food webs. They are therefore classified as persistent organic pollutants (POPs) and can still be detected at appreciable concentrations both in the environment and in organisms, especially at high latitudes and high elevations (due to the grasshopper effect, discussed above). The number of chlorine atoms in an OC molecule is positively correlated to its half-life and thus inversely correlated to its rate of metabolism or degradation, such that highly chlorinated compounds are more likely to persist in the environment than OCs with fewer chlorines. Conversely, less chlorinated compounds are selectively depleted as OCs travel toward the poles and through food webs.

DDT was widely employed in the 1940s and 1950s as an insecticide that was effective against hundreds of different pest species, including the vectors responsible for transmitting malaria and other deadly diseases. This OC achieved notoriety in Rachel Carson's book *Silent Spring*, which implicated DDT and other insecticides in the poisoning deaths of birds, fish, and other wildlife species in the years after World War II. Like many other EDCs, DDT is estrogenic. Specifically, it agonizes estrogen receptors and also increases expression of enzymes involved in estrogen synthesis. The primary DDT metabolite, DDE, antagonizes androgen receptors and thus is anti-androgenic. Due to their estrogenic and anti-androgenic effects, exposure to DDT or DDE at environmentally relevant concentrations is associated with feminizing and demasculinizing effects such as increased incidence of intersex, decreased sperm quality, and decreased fertility in male fish (Sun et al., 2016).

Until the late 1970s, over 200 congeners of PCBs were produced (primarily in the US but also in Europe) for use in capacitors, transformers, hydraulic fluids, and lubricants. PCBs resist degradation and are stable even at extreme pHs and temperatures. They typically enter the environment by leakage from or improper disposal of aging electrical equipment, and their resistance to degradation allows them to persist in the environment. Like other POPs, PCBs are lipophilic and thus bioaccumulate and biomagnify. For example, PCBs biomagnify by one or more orders of magnitude as they move through the polar food web from fish to seals to polar bears (Letcher et al., 1998). Although PCBs have not been extensively produced or used in manufacturing for several decades, they continue to be detected in the fatty tissues of marine organisms, especially those living and feeding in polar waters or in bodies of water that experience limited exchange.

The various PCB congeners exert their endocrine-disrupting effects by interfering with several hormone signaling pathways. For example, PCBs with fewer chlorine atoms weakly agonize estrogen receptors, whereas PCBs with more chlorine atoms weakly antagonize estrogen receptors. Most PCB congeners also antagonize androgen receptors. Multiple PCB congeners also interfere with the activities of thyroid hormone transporting proteins (known as transthyretins) and the activities of enzymes involved in steroid synthesis and metabolism. Thus, various PCBs can be considered estrogenic, anti-estrogenic, anti-androgenic, and/or thyroid-disrupting EDCs. Effects of exposure to PCBs can include anemia, immune suppression, hypothyroidism, and reduced fertility, especially in apex predators with high PCB body burdens, such as many marine mammals (Reijnders, 1986; Schwacke et al., 2012).

Organotins

Organotins (OTs) are organometallic compounds that contain at least one covalently bonded tin atom. Historically, OTs were extensively employed as antifouling additives in paints used on marine vessels and in mariculture facilities. Although OTs were banned from use in marine paints in 2008 by the International Convention on the Control of Harmful Anti-fouling Systems on Ships, developing countries that are not members of the International Maritime Organization can still use OTs for this purpose. In addition, OTs are still used globally as industrial and agricultural biocides, industrial catalysts for the production of polyurethane foams and silicone, and PVC stabilizers. OTs, especially those that are trisubstituted (i.e., they contain three tin atoms), are more toxic than inorganic tin to living organisms. In fact, OTs are among the most toxic anthropogenic chemicals that impact marine systems, as exposure of marine organisms to OTs is associated not only with endocrine disruption but also with dysfunction of the immune system, the nervous system, and metabolism. OTs exert their toxic effects through a number of mechanisms, including inhibiting CYP enzymes such as aromatase (the enzyme that converts androgens to estrogens) that are involved in steroid synthesis, inhibiting phase I and phase II metabolizing enzymes (thereby interfering with detoxification pathways), inhibiting steroid excretion, and agonizing the retinoid X or ultraspiracle receptors, which normally interact with other nuclear receptors such as peroxisome proliferator-activated receptor (PPAR- γ) and the arthropod ecdysone receptor. As a result of the myriad effects of OTs on synthesis and metabolism of steroids and activity of nuclear receptors, exposure of marine organisms to OTs is associated with altered gonad morphology and thus reproductive dysfunction; increased adipogenesis, lipid accumulation, and weight gain; and molting problems, especially in marine crustaceans (Yi et al., 2012; Berto-Júnior et al., 2018; Vogt et al., 2018).

OTs are susceptible to photolysis, which involves stepwise dealkylation of OTs to less toxic inorganic tin; however, this process is slower in sediments than in the water column and OTs have a strong affinity for sediments. As a result, OTs accumulate in benthic sediments; the sediments found in harbors, estuaries, marinas, and other coastal waterways have especially high concentrations of OTs given their proximity to shipping activities. Because they are hydrophobic, OTs bioaccumulate. In particular, they bind to sulfhydryl groups like those found in glutathione and proteins; thus, OTs accumulate in glutathione- and protein-rich tissues such as the liver and kidneys. Interestingly, OTs also bind to the protein keratin, which is found in hair and feathers; thus, birds and mammals are able to excrete OTs better and may therefore be less susceptible to the toxic effects of these chemicals than other marine organisms. OTs are also poorly biotransformed, in part due to their ability to inhibit detoxification pathways, and thus biomagnify as they move through food webs.

Of the OTs, tributyltin (TBT) is the most well studied and is arguably the most well known EDC that impacts invertebrate animals. The notoriety of TBT stems from its detrimental effects on reproduction in marine gastropod molluscs such as whelks. Specifically, exposure to TBT, even at low doses, induces a form of metabolic androgenization known as imposex, or the development of a vas deferens and penis, in female gastropods. This finding has been confirmed in over 200 species of marine gastropods and likely results from the effects of TBT on steroid synthesis and metabolism in these animals, although other mechanisms may also be responsible.

Future Directions and Final Comments

This article focused on the sources, fates, and effects of the most well studied anthropogenic chemicals that are found in marine systems and are known to interfere with the endocrine systems of animals. The list of such chemicals is long and growing, and a number of confirmed EDCs were not discussed here. For example, many insecticides (such as the juvenile hormone analogue, methoprene) target the processes of molting and metamorphosis to prevent maturation of larval arthropod “pests.” These insecticides can have detrimental effects on non-target species such as marine crustaceans, which employ the same pathways used by “pest”

species to regulate growth and development. Indeed, these unintended consequences of exposure to anthropogenic chemicals make the increasing prevalence of insecticides and other EDCs in marine systems especially concerning.

While much has been learned in the last several decades about the presence of EDCs in marine systems and the effects of EDCs on some marine organisms, many knowledge gaps still exist. For example, concentrations of most EDCs in deep, oceanic waters are rarely measured, and how these concentrations differ spatially and temporally is largely unknown. Furthermore, the fates of most EDCs in marine systems are not well understood, particularly for chemicals that partition into sediments or other compartments that are logistically challenging to study. The effects of EDCs on most marine organisms are also not well known, particularly for marine invertebrates. Although invertebrates represent 95% of the animals on the planet, we know very little about how environmental contaminants affect performance in these animals. This deficiency likely stems from a general lack of knowledge about invertebrate endocrine systems, which are more dependent on peptide hormones and less dependent on steroid hormones (with the notable exception of ecdysteroids) compared to the analogous systems of vertebrate animals. To better understand the scope of human impacts on marine systems, these knowledge gaps must be addressed. In addition, priority must be given to developing remediation strategies that both reduce the inputs of anthropogenic EDCs into marine systems and mitigate the effects of these chemicals in marine organisms.

Abstract

Soundscapes represent the sum of biotic, abiotic, and human generated sound in the landscape. Monitoring sounds can lead to insights both on habitat integrity and an early warning of threats to them. Where soundscapes are endangered, technology has made soundscape recording and analysis more accessible and affordable, resulting in the ability to continuously monitor wide areas for habitat health and human activity. Coupled with global communications and computing platforms, soundscape monitoring and analysis permits low cost and continuous monitoring of natural habitats. This is important because as climate change and human activity disrupt more and more habitats it provides a rigorous but cost-effective way to quantify and monitor changes to minimize habitat loss and extinctions.

Introduction

The field of soundscape ecology combines elements of bioacoustics, the study of animal vocalizations, with environmental acoustics, the scientific study of how sound is carried through the landscape (Krause, 2017). Every place in the world has a unique audio signature. This is composed of a combination of several types of sounds. Biophony includes biological sounds, the voices of animals. Geophony refers to geophysical or abiotic noise. For many places, for much of the year, the only natural sounds may be geophysical, including wind, storms, and water such as rivers or oceans. Anthrophony are the sounds made by people, including both the voices of people along with everything manmade, which now can be heard in even the most remote corners of the world with the sound of engines and planes. Increasingly it is hard to escape man-made noise anywhere in the world. For example when recording in the California mountains we have had recordings of biological sounds dominated by the sound of loggers with chainsaws on adjoining land, and in remote regions of the Amazon rainforest boat engines may be heard miles away (Fig. 1).

Soundscape ecology can be seen as a specialized branch of landscape ecology. As with the study of habitats, soundscapes can be classified based on geography, looking at the way ecology shapes them according to both physical factors and the influence of people (Pijanowski et al., 2011). As discussed elsewhere in this encyclopedia, anthromes are biomes shaped by how people interact with ecosystems, and need to be considered to fully understand biogeography (Martin et al., 2014).

Just as disturbance shapes biomes, it also influences the integrity of natural voices. As a pragmatic science, it seeks both to understand how human disturbance interferes with the functioning of soundscapes, and how measuring this can help both predict, measure and remedy these disruptions.

Anyone who has enjoyed a dawn chorus of birds in the spring time, or a night chorus of insects, can appreciate that animal sounds can be a striking part of a soundscape. While they may be viewed as a relaxing accompaniment to a natural setting or even just background noise, to the animals they serve a very serious purpose justifying the energy expenditure to make loud and repetitive sounds.

The rich soundscape of a tropical rain forest or spring in a temperate forest represents the complexity of communication in an environment with many competing species. Abundant spring peepers, for example, can be almost deafening in a temperate North American wetland in the spring. Like any other part of a habitat, the ability of a sound to carry far enough to be effective is a resource that can be as important as food or shelter for an animal. If a species cannot deter intruders or find mates in a habitat it will eventually become locally extinct. For this reason, animals have evolved strategies that differ from each other to make sure their specific vocalization can both get through and be understood by the intended recipient. As is often the case in nature, this simple need leads to marvelously complex and rich soundscapes where different species vocalize in different frequencies, at different times, and with different harmonics and rhythms (Fig. 2).

In the most ecologically diverse habitats, animals should be seen to occupy most spaces of the audio niche both temporally and spatially. In other words, there should always be an animal calling, at each frequency. In a sonically saturated habitat such as

Fig. 1 NPS sound data map.

Fig. 2 Peeper Spectrograph.

a tropical rainforest at dawn, all the sound niches may be so fully occupied that animal species may take turns, for example a bird of one species calling briefly and another calling at the same frequency when the first bird stops.

Animal vocalizations are a critical part of their survival and reproductive strategies. As a result, animals have evolved to develop distinctive vocalizations that carry as far as possible. The ability to transmit sounds to reach the maximum number of potential

mates or deter the most rivals conveys clear selective advantages. Using sound takes less energy than physically patrolling a territory so is a good adaptive strategy.

This paper discusses how animals divide the sound niche into acoustic habitats, and how these sonic patterns can be used to study and predict the health of animals and their biomes. Techniques are described to use soundscapes as a tool to protect species and their habitats.

Acoustic Niche Hypothesis

During field trips to a variety of tropical habitats in North, Central and South America, Asia and Africa, Bernie Krause and Ruth Happel developed an acoustic niche hypothesis viewing sound space like any other ecological niche, in which animals divide up available resources. With his background in music, and hers in ecology, they hybridized their knowledge and focused on how animals fill all the space available in a soundscape, much as musicians fill a musical staff with notes.

Over time, each species evolves its own acoustic bandwidth based both on the specific frequency and time of day to defend a sonic territory, to minimize being drowned out by other species or ambient noise.

As with any other ecological niche, animals compete for space, in this case acoustically. Looking at sonograms of animals in undisturbed and biologically rich habitats, there are no gaps in the sound spectrum. Every organism has its own place, either in time or frequency pitch, to avoid competing with the sounds of other species.

As Bernie Krause ([Krause, 2012](#)) refers to it, the ‘Animal Orchestra’ is a rich and unique ensemble that is never the same in two locations. This is the essence of why soundscapes are important and worthy of study—they are the living representation of complex animal interactions that have developed over millennia to help animals survive in a locality.

The most vibrant and diverse biological soundscapes are in the tropical rainforest. Almost every part of the temporal and spatial sound spectrum is filled with insect, bird, and other sounds. Tropical rainforests can be loud and some tropical rainforest animals—for example howler monkeys and gibbons—have vocalizations that can travel for miles.

At the opposite extreme there are deserts in the western United States that actively absorb sound. They are very quiet, sometimes disturbingly so. In between are many soundscapes in temperate and tropical regions that may vary widely in the volume and variety of biological sounds seasonally. Wet seasons, spring/summer, and migrations may cause a normally depauperate soundscape to become very active for a short period as insects hatch and mammals and birds come to feed.

Spectrographs and Recording Technology

While soundscapes have clear value in biological study, it is a relatively new field of study due to the reliance on technology to collect and analyze soundscapes. There has been a clear relationship between new technologies and soundscape studies. Prior to the ability to accurately record soundscapes and bring them back to the lab for analysis, soundscape analysis was more craft than science, limited to individual experiences in identifying sounds in natural settings.

Technology to record sounds was only developed in the late 19th century. While occasional attempts to record natural sounds on location were undertaken for movies and other artistic purposes, the expense and complexity of recording good quality sound in the wild limited this for most of the 19th and 20th centuries.

Ornithologists have long used bird song and bird calls as ways to identify and find birds, and they were pioneers in recording animal vocalizations in the wild. Much of their focus was on capturing individual bird calls, to assist in identification. They generally used parabolic or shotgun microphones that could capture the specific vocalization of the animal. Such microphones are good at a distance and were necessary with older recording technology such as magnetic tape and cassette recordings due to limited dynamic and frequency range of the recordings.

One of the initial reasons for this approach to animal sound recording was limitations in the ability to record sounds in the field. Until very late in the 20th century, field recording involved the use of analog magnetic tape—either reel-to-reel or cassette recorders. Analog recordings have the disadvantage of losing data every time they are copied, and depending upon the type of tape used some frequencies are recorded more effectively than others. In the early days of wildlife sound recording this bias in frequency and sound loss during copying of tapes made the focus animal sound identification instead of soundscape analysis. While someone with a high-quality reel-to-reel tape recorder could get good quality sound recordings, it was only a partial representation of the amount of sound present in the soundscape.

Only in the 1990s did portable digital tape recorders become widely available. Digital recordings also for the first time allowed full fidelity copies to be made of the original recording. Bernie Krause and Ruth Happel pioneered the use of digital recordings in the tropics during this period, and the recordings still provide a historical record of habitats that often no longer exist. This kind of longitudinal historical perspective is much easier with digital recording technology. These techniques have greatly advanced comparative analysis of sounds collected by different people in different locations at different times.

By the early 21st century flash memory in relatively inexpensive digital recorders and smartphones replaced digital tape. This lowered the cost and complexity, and made the recording process less subject to environmental issues like humidity. Along with the growth of the Internet and cloud storage, digital sound archives became more accessible to researchers.

With the ability to record a full sound spectrum without bias toward certain frequencies and with lossless copies, it is possible to get high quality recordings of the overall soundscape without focusing on a specific animal or call. Use of a shotgun or parabolic microphones usually requires the presence of a person to point the microphone at the desired animal or sound, while soundscape recording can be better automated for continuous or remote recording with omnidirectional microphones.

One additional emerging technology in soundscape ecology is passive acoustic monitoring (PAM). PAM has previously been used to monitor whales, as well as for terrestrial studies (Rodi and Herbst, 2012; Towsey et al., 2014). Although technologies differ between applications, PAM is increasingly used in ways that minimize human intervention, and use passive arrays rather than human observers. Such automated recording systems are still evolving, but show tremendous promise for a variety of scientific and conservation applications.

In recent years, with advances in batteries, solar power, and energy efficient digital electronics, automated recording has come increasingly into use worldwide. Automated recording devices generally work best with omnidirectional stereo microphones. Stereo (recording with two channels) permits movement of sound to be tracked in a soundscape and recording in all directions permits a wider area to be monitored. With increasing sensitivity of microphones and better noise filtering and higher resolution recording, specialized microphones have become less important.

Relying on trained observers to conduct biological surveys requires both a select group of individuals to conduct the surveys, and also leads to potentially unreliable comparison between data sets. Collecting recordings can provide more consistent results.

Automated recording technologies have been used since the early days of soundscape recording. When Ruth Happel was recording habitats in the southern US, she would frequently record the dawn chorus of natural sounds using automatic timers and pre-set microphones and digital recorders. This technique not only was less labor intensive, but also less disruptive of the natural soundscape. Many of the most common vocalizations heard by humans are alarm calls due to the presence of humans. Having automated or remote recording without a human present is often a much better way to capture an undisturbed natural soundscape.

In addition to recording technologies, techniques to visualize sound have also evolved over the years. Many recordings of soundscapes are represented by a spectrogram, a visual representation of sounds, in two or three dimensions depending on how it is displayed. When reading a spectrogram, it is not unlike reading music. The song moves from left to right in time, and the high-pitched notes are higher than the lower pitched notes. The width of each note shows the duration, rather than in musical notation having quarter, half and whole notes (Fig. 3).

One axis is time, the second axis is frequency, and sometimes loudness of sounds is represented through color, with intense colors showing the loudest vocalizations. The axis with sound is usually shown in seconds, though of course this might vary depending on the unit of time being represented. The ordinate shows the frequency or pitch, with higher pitched sounds representing higher frequencies. The frequency is measured in Hertz (Hz).

Fig. 3 Spectrogram of an Indonesian rain forest soundscape.

Patterns of vocalizations often vary widely by time of day and year. Dawn and dusk are favored by many species for acoustic properties aiding in transmitting sounds. Cooler air temperatures make the air denser, permitting sounds to travel farther. Certain times of year are also noisier, especially in temperate habitats, when spring through fall tend to have more species calling than in winter, often to declare territory or attract a mate. A wide range of variables affect soundscapes, including weather, plant phenology, vegetation structure and complexity, temperature, solar radiation, and humidity, habitat alteration, climate change, introduction of toxins, and spread of invasive species.

It's not necessary to have working knowledge of all recording or spectrograph techniques to appreciate the significance of acoustic niches. However, it is worth noting that the limits of such technology have historically meant that disruptions within the wild soundscape went widely unnoticed. It is only as recording technology evolves that we will gain the full picture of what we have already lost.

Habitat and Soundscape Degradation

Traditional biological surveys and research in both temperate and tropical regions reveals that soundscape diversity is related to habitat quality, with decreasing acoustic diversity in urban and agricultural locations, as well as disturbed forests. The biodiversity of sounds can be closely correlated with biological diversity.

People shape soundscapes, both directly with planes, trains and automobiles, along with indirectly altering the structure of the habitat with deforestation and similar activities that intrude on natural soundscapes, and continue to shape the sounds long after the human sounds are gone.

This evolutionary importance of animal vocalizations for survival and reproduction means that sounds themselves are a reliable indicator of the presence or absence of animals. Soundscapes become a way to measure relative, and sometimes absolute animal abundance and behavior. Soundscapes are not only worth preserving for their own sake—they are also a way to assess health of a habitat and a low-cost way to inventory animal populations that can be conducted and compared over extended periods. Acoustic monitoring can serve as an aural canary, with soundscape changes serving as a bellwether for deeper environmental problems, warning of current or developing issues with endangered habitats and species. Changes in animal sounds over time and space can help show underlying changes to habitats as a result of climate change, pollution, and ecological disruption such as deforestation.

A striking example of animals shaping their calls directly to avoid competing with human sounds is the research of [Ernstes and Quinn \(2016\)](#). A study of brown-headed nuthatches and other birds in South Carolina observed they shifted their vocalizations higher to avoid being masked by vehicle traffic. Traffic noise that carries farthest is usually low frequency, so the movement of vocalizations up to a less contested frequency would be a reasonable adaptive response. A similar change in animal behavior in response to traffic noise is seen in Australian frogs. They are observed to shift their calls to a higher frequency when in the presence of traffic noise ([Parris et al., 2009](#)).

In addition to effects on land, people are creating difficulties for communication of marine animals. In oceans, commercial shipping has led to increasing background noise over the last 150 years. Right whales adjust their calls in response to these changes, using a higher fundamental frequency and calling less often in high noise habitats, due to the low frequency noise that can interfere with their vocalizations. This study shows that the shift has occurred with whales in their lifetimes, so is not being created by evolutionary selection ([Parks et al., 2007](#)).

Notably, seismic surveying, ship noise, and other anthropogenic factors seem to disrupt the acoustic niche of both whales and dolphins, as recent studies ([Guarino, 2018](#)) have shown that dolphins become louder and whales become quieter with increased ambient noise. Potentially, as scientists become more aware of the ways in which anthropophony causes shifts in the acoustic ecosystem, soundscape studies will increasingly be consulted in both court cases and policy making.

Seismic surveying—the process of using reflected sound waves, such as from air guns fired into the sea floor, to search for oil and gas reserves—is potentially deadly for whales and other marine mammals. This practice has been linked to stranding events ([Mcgeady et al., 2016](#)), decreased concentration of zooplankton ([McCauley et al., 2017](#)), potentially disrupted polar bear denning ([Amstrup, 2018](#)), and other significant ecosystem shifts. For this reason, seismic surveying is emerging as one of the most litigated forms of anthropophony in recent years, with numerous environmental law firms filing suit to stop not simply offshore drilling, but the noise pollution accompanying it. The Sierra Club recently lobbied ([Moffitt, 2019](#)) to stop SAExploration from conducting seismic surveying in the Arctic Refuge, as just one example of soundscape ecology becoming increasingly relevant in energy policy and law. The Gullah/Geechee Nation's ([Cooper, 2018](#)) campaign against offshore drilling also emphasizes the potentially deadly impacts of such surveys on whales and dolphins. Around the world, numerous coastal stakeholders are increasingly concerned not simply by the risk of oil spills from offshore rigs, but also by noise pollution, and more overlooked ways in which such practices disrupt the coastal soundscape.

Whatever the normal level of diversity when human generated sounds enter a soundscape, they can represent a challenge to existing occupants of a sound spectrum. For example, if a road is built through any of the habitats mentioned above, it has the potential to disrupt the animals living there who depend upon sound to defend territories and find mates. Disturbances from human activity to a soundscape can disrupt animal survival strategies, change animal behavior, and cause animals to become less abundant or even go locally extinct.

Soundscapes as a Conservation Tool

In order to use recordings as a tool to understand habitats and their associated sounds, and how they are changing due to human influence, there must be better ways to standardize measurement. One means of doing this is to set up arrays of recorders around the world, to continuously monitor a variety of habitats. This is faster and more effective than assessing biodiversity with visual surveys, or by relying on trained teams of experts.

As passive acoustic monitoring, or PAM, becomes more advanced, such technologies will likely become increasingly prominent, and play a larger role in environmental law and enforcement mechanisms as noted. Already, PAM is used by marine mammal observers at night, or in other adverse conditions when visual monitoring is not possible. By listening for whale calls, observers can help seismic surveying companies comply with the Endangered Species Act, the Marine Mammal Protection Act, and other such statutes that regulate the take of whales and other protected species. Passive acoustic monitoring has additionally been used to monitor various terrestrial ecosystems, and has been used in bird and other animal studies (Pieretti et al., 2015; Towsey et al., 2014). Typically, such studies are less tightly regulated than PAM for marine mammals, which may be subject to Bureau of Ocean Energy Management regulations and other restrictions. As PAM becomes more widely implemented, however, it may become more commonly used as an enforcement tool in terrestrial ecosystems, and aid in the detection of poaching or illegal logging.

Systematic collection of recordings allows analysis of sonic patterns, both to determine a baseline and to understand what makes a healthy habitat. Sounds can be classified as biological, geophysical, and associated with people. In studying sounds and their association with habitat health, it should be possible to both assess biodiversity, and map out changes over time to see what impacts affect biodiversity most. Conservation efforts can use bioacoustics both to understand and protect wildlife habitats (Kocsis, 2017).

Longitudinal studies, looking at how sounds differ from seconds to hours, extending to time of day, season, and yearly, it may be possible to observe how soundscapes are changing in response to people on both a small scale locally, and longer-term impacts of climate change, to understand through sound how changes to habitats are affecting species.

At the present time organizations like Rainforest Connection are pioneering real time recording and transmission of sounds for analysis using cellular connections. While cellular connections can be used for this purpose, it is expected that soon low earth orbit satellites will make real time transmission of sounds to cloud based sound archives available over much wider areas than are currently possible (Weitering, 2019). Already Rainforest Connection uses their cloud platform for real time monitoring of forests where they work, with better connectivity using satellites, this should be possible over a much wider area with inexpensive solar or battery powered devices (Nunez, 2017).

Satellite images and drones can observe and measure deforestation, but may miss equally important ecological factors like hunting, fires, and invasive species. Field studies and surveys can pick these up but are usually limited in time and location. Recording devices can capture animal vocalizations from several hundred meters away, day and night. They can record at set times, or continuously, if there is solar power or a cellular network signal. While sound recordings can be large in size, they are relatively straightforward to analyze compared to image or video files and are not subject to changes in light in order to collect usable data. Sound analytic techniques have progressed quickly with advances in computer technology, and sophisticated audio analysis is now possible with even handheld devices.

If companies have a program that requires legal compliance with no deforestation, they can be monitored by bioacoustics to determine how much forest remains. Audio monitoring can catch hunting, habitat degradation, and fires below the canopy that might be missed by satellites or other visual data collection and help with action against activities like illegal logging and poaching (Burivalova et al., 2019).

Soundscape Monitoring—Progress and Potential

An analytical platform for global soundscape monitoring would advance research in a number of areas, along with providing a baseline that could be used for environmental improvement and conservation enforcement. An ideal platform would provide capabilities for secure transfer of sounds from any location to a repository where they can be analyzed and compared with previous recordings in the same location and with similar habitats in other localities.

In order to effectively study and compare soundscapes and use this data to monitor and understand habitats, significant amounts of data must be collected and analyzed. Recorders can now be set up in remote areas and run by either battery arrays or solar power, so they can be collected continuously. Automated recording equipment is already being used in conservation and research (Palminteri, 2016; Jahn et al., 2017; Brandes, 2008). Software is being developed to measure the diversity of soundscapes (Kocsis, 2017).

Potential dimensions of analysis include spectral analysis, which can be used to determine how much of the sound spectrum is being used by wildlife. It should also include temporal analysis to investigate patterns of animal sounds throughout each day and throughout the year. If simultaneous recordings are done at different locations, animal abundance can be estimated by triangulation of the different animals on overlapping recordings. Once baselines have been established, it would be straightforward to identify specific species at different localities, and to often estimate their abundance. This would lead to identifying marker species for specific types of habitat change and lead to definitions of the soundscape of a healthy habitat, and to permit diagnosis of unhealthy habitats (Palminteri, 2016). Using machine learning and statistical analysis it would be able to characterize specific habitats patterns and find similarities between soundscapes in both time and space.

With adequate refinement even single species abundance could be monitored across different soundscapes in some cases (Zwart et al., 2014). Software has been used successfully to identify the calls of a single species in a series of thousands of daily recordings (Jahn et al., 2017) to research behavior of birds in the Pantanal of Brazil. Automated recording technology coupled with automated analytics and species identification could be extended and expanded. Once the software is developed to identify a single species it could potentially be reused indefinitely on new recordings to extend species ranges or monitor trends in species abundance in a variety of habitats.

If multiple recorders are set up in an area at intervals, it would also be possible to record movement of vocalizing animals through the forest by comparing simultaneous recordings. The amount of data that could be extracted from continuous recording is mainly limited by the number of animals vocalizing, and how much interest and effort there is in analysis.

If records are kept of what remediation steps can achieve results, then those same steps can be applied to different locales with similar soundscapes. Soundscape analysis would allow a quantifiable measure of environmental health with a minimum amount of personnel at a locale. As noted in Burivalova et al. (2019) it would be ideal for monitoring compliance of industries that are regulated to meet environmental standards, in addition to providing valuable research information on a global scale.

A new and important tool is the development of acoustic indices, to measure acoustic energy in field recordings. Standard tools to quantify 24 h recordings will allow systematic comparisons of data across habitats and research studies. This can be used to estimate biodiversity in a controlled and comparable way. Research suggests there are optimal ways to collect and analyze recordings to maximize information (Pieretti et al., 2015).

Acoustic indices can measure and predict species diversity in a broad view of both space and time, which is especially important in biodiversity hotspots where rapid development and habitat loss, in association with climate change, threatens a broad range of biomes and species (Buxton et al., 2018). This provides a quick and accurate means of assessing biodiversity often more accurate than more costly and time intensive methods of traditional ecological assessment.

Conclusions

Soundscapes, and the unique habitats they represent, may be changing and in some cases endangered, but advances in technology permit them to also be used to help save biodiversity. While soundscape recording used to be an expensive and time-consuming activity, it is now possible to use sound and soundscapes as a way to document and monitor a wide array of habitats.

Soundscapes represent not only a unique resource and signature of a habitat, they also provide a way to record an essential characteristic of a habitat through time. This can serve as a historical record and also be used as a monitoring tool with minimal environmental disruption. In association with other developing technical resources, including camera traps and drones, continual audio recordings can assist in alerting and locating disruptions to habitats and species through hunting, logging, mining, and other threats. A library of sound recordings can be used to document and correlate with biological data, to determine patterns of biodiversity in association with sonic signatures. Recordings can also be used in real time to alert local wildlife managers to immediate habitat threats, so they can act on them before the animal or habitat is lost. This is a valuable resource that should be fully leveraged in the effort to preserve wildlife and habitats.

Abstract

Across anthromes there has been an increase in the number and miles of roadways with a corresponding increase in vehicle traffic. Roads and associated traffic and traffic noise has been shown to affect avian abundance, breeding success, density and species diversity. An expanding body of literature has demonstrated that many bird species alter the way they vocalize in order to be heard by conspecifics and other species in response to the noise generated by traffic and other human activity. This review summarizes the literature that describes the effects of traffic noise on birds across anthromes. Documented changes in vocalizations due to traffic noise include shifts in amplitude, frequency, rate, timing, and duration of vocalizations along with a number of behavioral adaptations. Costs of altering vocalizations include the inability to attract a mate, poor vocal performance, not sounding like conspecifics, and being more easily heard by predators. Outstanding research needs in this area include (1) controlling variables that might affect negative impacts on birds along roadways, (2) analyzing vocal communication during the non-breeding season, (3) identifying consequences of and responses to acoustic masking (e.g., inability to protect a territory or faulty parent-offspring communication), and (4) applying research to mitigation efforts.

Introduction

Anthromes are geographical categories that represent globally significant ecological patterns created by sustained direct human interactions with ecosystems (Ellis and Ramankutty, 2008). Much like global land use and land cover change, humans have altered much of the world's acoustic characteristics with anthropogenic sounds; sustained sounds that are different in pitch, amplitude, acoustic structure, distribution, and often more continuous than sounds produced in natural environments (Nemeth et al., 2013; Pijanowski et al., 2011; Slabbekoorn and Ripmeester, 2008). Roads and associated traffic in particular have a broad acoustic impact, affecting nearly one-fifth of the total land area in the United States (Forman et al., 2002). The resulting acoustic impacts from roads and associated traffic may be broad, extending outwards as far as 450 m into the landscape adjacent to roadways (McClure et al., 2013; Slabbekoorn and Ripmeester, 2008; Summers et al., 2011). Aspects of traffic effects, volume and noise, as well as urban noise disturbance effects on avian species have been a focus for studies in the past 20 years; with a trend towards studying the disturbance effects of traffic noise specifically (Fig. 1).

Birds have among the most elaborate and complex acoustic signals in the animal kingdom (Marler, 2004), communicating primarily through songs and calls. These vocalizations occupy nearly all available acoustic niches (Farina et al., 2011). Calls are simpler and shorter than songs and can convey a variety of messages (Marler, 2004). Songs are longer, more melodic, and are mainly used for attracting females and deterring rivals (Marler, 2004). Most songs and calls produced by birds range between 1 and 9 kHz (Rheindt, 2003; Zollinger et al., 2012). Since traffic noise is generally characterized by a low frequency band of noise between 0 and 4 kHz (Nemeth et al., 2013; Nemeth and Brumm, 2010; Patricelli and Blickley, 2006; Pieretti and Farina, 2013), the lower frequencies of bird vocalizations may overlap with traffic noise resulting in acoustic masking. This concept can be seen in Fig. 2 where the lower-pitched portion of the Blue Jay's (*Cyanocitta cristata*) vocalization is drowned within the low frequency traffic noise.

Acoustic masking occurs when one sound masks, or interferes with, another sound (Fig. 2). Species with lower-frequency vocalizations (1–2 kHz) will have greater acoustic interference, or masking, than those with higher-frequency vocalizations (higher than 4 kHz) that are above typical traffic noise levels (Templeton et al., 2016; Halfwerk et al., 2011a; Luther and Baptista, 2010; Parris and Schneider, 2008; Polak et al., 2013). Different species of birds have different sensitivities to traffic noise. Any acoustic masking of their vocalizations presents the possibility of negatively affecting their communication and reproductive fitness, as verbal

Fig. 1 Years of publications for studies show a trend over time of studying traffic effects on avian species, to urban and anthropogenic noise effects, to specifically traffic noise effects on avian species. Papers obtained from the Web of Science following a key word search for the terms avian, communication, vocalization, traffic, roads, and noise.

Fig. 2 The low frequency, constant traffic noise, as seen across the bottom of the sonogram, drowns out the lower frequency portions of a Blue Jay's call.

communications can only be beneficial if the receiver detects the vocalization. Thus acoustic masking of vocalizations by traffic noise has proximate and ultimate implications (Templeton et al., 2016; Ryan and Brenowitz, 1985; Rheindt, 2003) and it is essential that we recognize the impacts of increased traffic noise on avian communication. In this review we summarize the growing body of literature that focuses on impacts of traffic noise on bird vocalizations and identify key gaps in knowledge.

Methods

We searched Google Scholar (<http://scholar.google.com/>) for combinations of the following key words: avian, communication, vocalization, traffic, roads, and noise. The identified articles were divided into two major themes: proximate and ultimate responses to traffic noise. We summarized research on proximate responses into six categories: changes in frequency, amplitude, timing, structure, learning, behavior, and mechanisms of response to change. We also touch on an ultimate response of divergence between urban and nonurban songs due to acoustic masking by traffic noise.

Proximate Outcomes of Acoustic Masking

Frequency shifts. The most common response of birds to traffic noise is to vocalize at a higher frequency, or pitch, which includes: increasing the minimum frequency (Ernstes and Quinn, 2016; Oden et al., 2015; Dowling et al., 2011; Luther and Baptista, 2010; Luther and Derryberry, 2012; McLaughlin and Kunc, 2013; Slabbekoorn and den Boer-Visser, 2006) changing the maximum frequency (Dowling et al., 2011), shifting the entire vocalization to a higher frequency (Francis et al., 2011; Goodwin and Podos, 2013; Halfwerk et al., 2011a; Parris and Schneider, 2008; Rheindt, 2003), or increasing the frequency of peak notes (Nemeth et al.,

2013). Shifting all, or parts, of a vocalization up in pitch allows for fewer, lower-pitched notes that could potentially be masked by anthropogenic noise (Pieretti and Farina, 2013; Slabbekoorn and den Boer-Visser, 2006).

Species with lower-pitched calls are more likely to shift their vocalizations. Parris and Schneider (2008) showed that the lower-pitched Gray Shrike-thrush (*Colluricincla harmonica*) sang at a higher frequency (pitch) when near traffic noise. In contrast, the higher-pitched Gray Fantail (*Rhipidura fuliginosa*) did not change its song in the presence of traffic noise. The differences in type of shift are demonstrated by both Great Tits (*Parus major*) and Common Blackbirds (*Turdus merula*). While both species sing at higher pitches in urban areas, Common Blackbirds shift their whole song upwards in frequency while Great Tits only increase their minimum frequency (Nemeth and Brumm, 2010; Slabbekoorn and Peet, 2003). Males that adjust the frequency of their songs in order to exploit a spectrally favorable frequency could possibly reduce the attractiveness of the song (Halfwerk et al., 2011a). For example, female Great Tits may cheat on their mates if the male does not sing a low pitch song (Halfwerk et al., 2011a).

Amplitude increases. Birds adjust and adapt the amplitude (volume) of their vocalizations daily to compete with ambient noise (Brumm and Todt, 2002; Brumm, 2004; Nemeth and Brumm, 2010; Zollinger and Brumm, 2015). For example, the Noisy Miner (*Manorina melanocephala*) will call more loudly at noisier locations near busy roads than near quieter residential streets (Lowry et al., 2012). Increasing amplitude in response to an increase in ambient noise is known as the Lombard effect (Lombard, 1911). The Lombard effect is usually accompanied by a change in pitch of all or part of a vocalization since lower frequency vocalizations (1–4 kHz) tend to have less energy (Nemeth and Brumm, 2010). It has been suggested that amplitude is the key factor in exchanging verbal information and that amplitude has a larger, stronger effect on communication distance than frequency (Nemeth and Brumm, 2010). For example, Great Tits that increased their amplitude could communicate further distances, even in the presence of high traffic noise (Nemeth and Brumm, 2010).

Timing adjustments. Birds can change the timing of their vocalizations to avoid competing with their neighbors, to take advantage of small gaps in ambient noise, or to not sing when predators are more active or a mate is not near (Brumm, 2007; Ficken et al., 1974). Least Flycatchers (*Empidonax minimus*) will sing between the songs of Red-eyed Vireos (*Vireo olivaceus*) so as to not have overlap of the two species' songs (Ficken et al., 1974). In response to traffic, European Robins (*Erithacus rubecula*), have been shown to change the time of day they vocalize by singing at night when traffic noise levels are low (Fuller et al., 2007). Spotless Starlings (*Sturnus unicolor*) and House Sparrows (*Passer domesticus*) have an earlier start to their dawn singing near high traffic noise (Arroyo-Solís et al., 2013).

Vocalization structure modifications. Species may vary vocalization structure by changing rate or rhythm, increasing the length of all or parts of the vocalization, or increasing redundancy in one song or call before switching to another (Brumm and Slater, 2006; LaZerte et al., 2017). Changing the rate and/or rhythm of a song or call can include temporal structures, note timing, or syllable timing within the vocalization (Patricelli and Blickley, 2006). Chaffinches (*Fringilla coelebs*) use serial redundancy to ensure their message is received while in noisy areas (Brumm and Slater, 2006). Pacific Wrens (*Troglodytes pacificus*) will decrease the length of their vocalizations (Gough et al., 2014) while European Robins will decrease both the length and complexity of their vocalizations near high levels of noise in order to send a clear message (McLaughlin and Kunc, 2013). While making a change may allow a bird to be heard, it could also increase the risk of having a poorer vocal performance that may not be as attractive to females (Byers, 2007).

Learning constraints. Vocalizations that are masked may be copied incorrectly or never learned (Slabbekoorn and Ripmeester, 2008). Copying imprecision may result from a bird hearing, and therefore only learning, part of a song. Those bird species that are able to learn multiple songs may be at an advantage in areas of high traffic noise. If a certain song does not elicit a response, those birds with multiple songs in their repertoire are able to drop that song and still have others to choose from (Slabbekoorn and Ripmeester, 2008).

Behavior alterations. Birds may also alter behaviors associated with vocalizations in order to have their vocalizations heard. Birds may turn their heads in order to send their vocalization in the direction of the receiver (Dooling, 2005) and it has been found that European Robins will move away from the source of noise before vocalizing (McLaughlin and Kunc, 2013).

Mechanism of Response to Change

Vocalization Plasticity. Some avian species are born with innate vocalizations and are unable to modify them during their life (Kroodsma, 1984). These species, mainly non-passerines, require no auditory examples for vocal development (Kroodsma and Konishi, 1991). However, there's a large group, composed of mainly passerines, which must learn their songs and calls from listening to others of their own species: their parents, neighbors, or members of their flock or social group. Within these vocal learned species, some are able to modify their songs multiple times throughout their life, while others stop developing that ability early in life. This is due to a plastic period of vocal development where learning after a certain developmental landmark is reached cannot occur (Ríos-Chelén et al., 2012; Slabbekoorn and Peet, 2003). Song Sparrows could be age-limited song learners since the songs in their repertoire are identical year after year (Nordby et al., 2002). Noisy territories do not hinder birds with innately higher-pitched vocalizations or birds that learn to restrict vocal output to a frequency range that overcomes the masking effect of ambient noise. Those species without vocal plasticity may not be able to avoid acoustic masking and may have to search for more suitable, quiet habitats.

Anatomical limits. Some birds may have anatomical or physiological limits in their ability to vocalize at higher frequency ranges to be heard over traffic noise. This could include the angle they can hold their head, how wide they can open their beak, their beak shape, and their body size. Typically, the frequencies that birds are able to produce are related to their body size. The larger the body size, the lower the frequency of the bird's songs or call; and, the smaller the body size, the higher the frequency of their vocalizations

(Ryan and Brenowitz, 1985). There is also an association between body size and amplitude (Brumm, 2004). The larger the body is, the greater the amplitude and vice versa. A bird cannot change the vocal mechanisms in their throats that allow for certain characteristics of a song to be produced (Podos et al., 2004). Having an anatomical or physiological limit for making a vocalization could cause birds to avoid areas with high levels of traffic noise.

Ultimate Outcomes of Acoustic Masking

Bird vocalizations, like all attributes of living organisms, can evolve due to a changing environment. The acoustic properties of the environment, and their masking effects, can influence the evolution of vocal signals (Brumm, 2004; Goodwin and Podos, 2013; LaZerte et al., 2017; Pijanowski et al., 2011; Slabbekoorn and den Boer-Visser, 2006). Song learning altered by traffic noise is at least partly responsible for the song divergence between populations of species living in cities and forests (Nemeth et al., 2013; Slabbekoorn and den Boer-Visser, 2006). Copying imprecision can lead to variation in songs which can then lead to the development of dialects that are easier to detect over the noise (Luther and Baptista, 2010; Podos et al., 2004; Slabbekoorn and den Boer-Visser, 2006). Reproductive isolation of species can be due to divergence between urban and nonurban songs, urban songs being higher pitched than nonurban songs (Slabbekoorn and Ripmeester, 2008).

Is a Focus on Noise Drowning Out Other Factors?

While the focus of this review is on the impacts of traffic noise on avian vocalizations, there are other issues that should be considered. Roads and road noise also impacts avian density, richness, abundance, distribution, diversity, breeding success, reproductive success, and stress (Halfwerk et al., 2011b; McClure et al., 2013; McLaughlin and Kunc, 2013; Polak et al., 2013; Reijnen and Foppen, 1995; Reijnen et al., 1995). It is suggested by many authors that it is the actual noise from traffic that has the greatest negative impact on birds (Forman et al., 2002; Halfwerk et al., 2011b; McClure et al., 2013; Parris and Schneider, 2008; Polak et al., 2013; Reijnen and Foppen, 1994, 1997; Reijnen et al., 1995). However, others suggest the most negative impacts on birds in habitats adjoining roads may be due to factors other than traffic noise (Crino et al., 2013; Fernandez-Juricic, 2001; Foppen and Reijnen, 1994; Forman et al., 2002; Francis et al., 2009; Goodwin and Shriver, 2010; Halfwerk et al., 2011b; Herrera-Montes and Aide, 2011; Miller et al., 2003; Reijnen and Foppen, 1994, 1995; Reijnen et al., 1995; Rheindt, 2003; Summers et al., 2011). These negative impacts of roadways include: air pollutants, microclimatic modification, visibility of cars, road kill, and predators attracted to road vicinity.

Needs for Future Research: Proximate and Ultimate Outcomes of Acoustic Masking

Territory guarding. Male birds changing their territorial songs to overcome acoustic masking is a predicted response to traffic noise that has not yet been tested. If a male near traffic noise sings normally he risks the possibility of not having his song heard. If he alters his song, the message may not be received correctly. If the song is not heard or understood, it could lead to having to fight off intruding males to keep them from encroaching into his territory, which would detract from the time spent singing to attract females (Slabbekoorn and den Boer-Visser, 2006). There are studies on traffic noise affecting mate fidelity and choice, but information is needed to see if traffic noise could cause males that have changed their songs to lose their territory during the breeding season or to suffer reduced fitness.

Inter- and intra-flock communication. Changes in communications between and among species are another predicted response of traffic noise whose effects remain understudied. Vocalizations can inform the receiver of the whereabouts, identity, and distance of the sender in order to keep in contact with a mate, a flock mate, or a social group (Halfwerk et al., 2012; Slabbekoorn and Halfwerk, 2009). Parents and their offspring use acoustic signals to recognize and communicate with each other (Kilner, 1999). Young birds beg for food and attention from their parents with distinguishable vocal sounds (Marler, 2004). If the vocalizations are not heard, or the sender has made the vocalization sound different, information may not be transferred correctly. It has been found that noise causes Tree Swallow (*Tachycineta bicolor*) nestlings to fail to respond to parental cues (Leonard and Horn, 2012). However, the consequences of this failed connection are unknown. Studies are needed on how traffic noise could potentially interrupt conspecific communications, intra-flock communications, or inter-species communications and the consequences of those interruptions.

Winter. Migratory birds have four parts of their migration cycle: spring migration, summer breeding, fall migration, and overwintering. Research and management for birds has largely focused on the breeding season and their migration patterns (Faaborg et al., 2010). There is a lack of information and research during the wintering season. Winter months are important for migrating birds as they build nutrient reserves for the spring migration (Faaborg et al., 2010) and breeding season. For non-migrating birds, the winter season provides security and time to acclimate to the resources and hiding places in a bird's home range. More information is needed on how traffic noise interrupts birds' communication in the winter when the focus is not on mating and territory but rather food location, predators, and contact calls (e.g., Oden et al., 2015). Interruption of winter vocalizations can cause identity confusion, disrupt food information transfer, and cause predator warnings to be misinterpreted or not heard.

Traffic noise vs traffic volume. Research that better controls other stimuli associated with noise such as physical alteration of habitat or visual disturbance presented by moving traffic is needed (Francis et al., 2009; Nemeth and Brumm, 2010; Slabbekoorn and Ripmeester, 2008; Summers et al., 2011). To suggest traffic noise is the only factor contributing to negative effects on birds, researchers must design a study that blocks visual disturbances from traffic, keeps birds from colliding with traffic, have no pollution or food

Table 1 List of different mitigation efforts to reduce the impacts of traffic and traffic noise on avian species.

	Mitigation techniques	Source
On cars	Better engine features	Forman et al. (2002)
	Quieter mufflers	Forman et al. (2002)

	Noise tax based on season, type of car, tires, and speed	Halfwerk et al. (2011b)

coming from the cars, and find a way to not have a habitat edge near the traffic noise. Or, researchers can bring traffic noise into an area with no previous anthropogenic noise. In order to show that variables besides traffic noise contribute most to the negative effects on birds, a roadway with all of its pollution and flashing lights must be used, but it must be silent. Also, more specific information on why certain species thrive near traffic is needed.

Conclusion

The effects of traffic and traffic noise on birds and their vocalizations are not fully understood. Many methods have been proposed to reduce the impacts of traffic and traffic noise on avian communities (Table 1). Although many have suggested mitigation methods, there is a need for additional studies to test their efficacy in reducing the negative impacts on birds. Finding cost-efficient mitigation techniques for traffic noise may help decrease noise pollution and therefore reduce the consequences of acoustic masking. Along with mitigation efforts, research is needed to determine predicted responses of traffic noise and their effects on male territory guarding, on inter- and intra-flock communication, and during non-breeding times of the year. Despite gaps in our knowledge, we can conclude that traffic is having a negative impact on certain avian species and we need to begin implementing mitigation measures to prevent this problem from worsening.

Abstract

The union of strategies of inequality reduction and promotion of renewable energy may have a greater impact on the decrease of social needs, promoting the appropriation of benefits by local communities. In this context, there is a need for the participation of local communities in the scope of public policies for the establishment of priorities that potentiate these strategies, particularly energy landscape and social acceptance. According to [Stiglitz \(2016\)](#), the greatest danger in the world is inequality, which overcomes all other dangers. It is therefore reinforced that the reduction of inequality should be a priority for all.

This way the aim of this article is to evaluate the impact of the advance of the use of renewable energy resources in the Brazilian semi-arid region in the historical context of scarcity and poverty in the region and, secondly, considering the abundance of energy resources. It seeks to understand the way in which the benefits derived from the exploitation of these resources are appropriate, based on a “built consensus” of imposition that is conceptually considered as a promoter of sustainability.

Introduction

Brazil is a country of recognized vocation for energy production and supply, with an emphasis on abundant renewable sources, which account for 43% of all energy offered in the country and 80.4% of all electricity consumed ([EPE, 2019](#)). In the energy context, the Brazilian Semi-arid is today the central stage of attention to the development of its high wind and solar potential. Of all installed wind power capacity in Brazil, 17.2 GW in 2019, 85.7% is in the northeastern semi-arid ([Brannstrom et al., 2018](#)). Together, considering the pace of solar expansion and the fact that the areas located in the Brazilian semi-arid region have the best solar potential in the entire territory, where average annual radiation values are comparable to the best regions in the world ([Pereira et al., 2017](#); [Constantino et al., 2018](#)), this technology will be intensely present modifying the territory.

Contrary to energy abundance, this same semi-arid area in an area close to three times the size of Germany, comprising 1133 municipalities in nine states of Brazil, with 82% of them registering a Human Development Index (HDI) of <0.65, houses a population in which 50% have no income or have as their sole source of income government benefits, mostly (59.5%) women ([de Araújo, 2011](#)).

The region is characterized by periodic natural irregularities configured by critical and prolonged periods of drought and has high temperatures, low thermal amplitudes, strong insolation and high rates of evapotranspiration and low rainfall, making its rivers provide low water availability. This unfavorable picture has historically marked its population and shaped a reality of scarcity and penury.

The condition of low development of the Brazilian Semi-arid does not result from a recent conjuncture. Water scarcity and stress in the region is a natural determination that holds. The unfavorable picture assumes such a historical and cultural breadth that the experienced poverty shaped the stereotype of the “sertanejo man”, the one that the drought literature tried to shape as a fort, highlights the drought and its shortage as a result of a natural fact. The adversity of the climate guides the life of its population, then

resigned to the natural rain cycle, reducing all employment and income generation alternatives that are linked to the annual rainfall regime. With this, agriculture and livestock strongly focus on subsistence.

The low level of development of the region is the result of discriminatory investment processes between Brazilian regions promoted by the central government. The South-Southeast axis received the full attention of the State to the detriment of the North and Northeast. These asymmetries in the allocation of resources, added to their natural characteristics and historical factors conditioned the local economy to be structured in a fragile manner, based on reduced social and economic sustainability activities. To get an idea of the gap that separates the northeastern semi-arid from the rest of the country, one can illustrate its per capita Gross Domestic Product (GDP), which in 2015 reached less than the US\$ 2000 per year, well below the Brazilian GDP per capita, which is US\$ 8500 (Cavalcante Júnior et al., 2019).

The Semi-arid region comprises 1262 municipalities, distributed over 1,128,697 km² and with a population of 27,870,241 inhabitants (SUDENE, 2017). Most of its territory is covered by Caatinga, a Brazilian biome considered as the more sensitive to human interference and global climate change. (The Caatinga originally covered an area of approximately 1 million km². Currently, its remaining area is 734,478 km², with < 1% being protected by protected areas. Deforestation for firewood is one of the main activities that contribute to desertification, drought and loss of Brazilian biodiversity (ASA, 2019).) About 1.5 million farming families (28.82% of all Brazilian family farming) occupy only 4.2% of the Semi-arid arable land, while 38% of the land belongs to rural settlements in the hands of a small elite (ASA, 2019).

The region continues to be neglected due to the lack of investments oriented to human coexistence with the natural reality of drought and drought regime (Cavalcante Júnior et al., 2019), where it is observed:

- Migration as an escape;
- Naturalization of the social and economic problems of the semi-arid region, making it possible to sustain a cloud that underpins the political pending issues of the power maintenance game, creating barriers to the region's development and coexistence with climate variability;
- Establishment of a development process strongly marked by the emigration of productive capital towards the Center-South of the country;
- In the 1930s, emergency projects aimed at the Semi-arid were implemented vertically, without appreciating the potential that these populations have historically built to cope with the natural drought condition;
- In the 1970s, the variability takes on even more dramatic contours and the "Drought Industry" is established.

The "good news" announced for the Semi-arid is its transformation into a renewable energy-producing space. However, the central issue to be discussed is not limited to the use of energy resources, but also to point out and understand to whom this energy is being produced, and what its purpose is (Harjanne and Korhonen, 2019).

The set of technologies that harness renewable energy allows us to look for a window of opportunity to associate the expansion of electricity supply, from the perspective of distributed generation, in vulnerable communities in the Northeastern Semi-arid region, particularly in places of extreme poverty, which enable the disruption of local populations to the cycle of poverty and scarcity. So, that social inequalities and opportunities for development are not limited between countries, but also intraregional.

In this atmosphere of reflection, it is valid to bring up local social demands, as there is a "world" of abundance as opposed to a "world" of scarcity. On the side of scarcity, it is possible to meet social demands through the Municipal Human Development Index (HDI-M), considering that there are still gaps in individual freedoms and choices. According to (UNDP, 2016), the idea of Human Development seeks to shift efforts beyond the economic sphere. The purpose of the HDI was to provide a counterpoint to another widely used indicator, the Gross Domestic Product (GDP) per capita, which considers only the economic dimension of development.

The combination of strategies to reduce inequalities, as well as the promotion of renewable technologies, both national and local, can have a considerable impact in reducing the heterogeneities of social conditions, promoting the appropriation of gains by local communities. In this context, the need arises for the participation of local communities in the context of public policies to establish priorities that enhance these strategies. According to Stiglitz (2016), the greatest danger in the world today is inequality, which overcomes all other dangers. This reinforces the view that reducing inequality must be a priority for all. In this context, Stiglitz (2016) states: "Inequality is very expensive. The price of inequality is the deterioration of the economy, which becomes less stable and less efficient, with less growth, and with the subversion of democracy. The large and growing divide between the richest 1% and 'the other 99%' is not just one of many concerns, but the defining feature of a completely sick economy."

The chapter, therefore, aims to evaluate the repercussions of the advancement of the use of renewable energy resources in the Brazilian Semi-arid in the historical context of scarcity and poverty of the region, and on the other hand, considering the abundance of energy resources. Thus, we seek to understand the appropriation of the benefits arising from the exploitation of these resources, based on a "built consensus" of imposition that is conceptually considered as a promoter of sustainability.

Brazilian Semi-arid: A Development Model to Be Overcome

It is observed that there is ambiguity in the development of renewable energy in the Semi-arid region, since, on the one hand, the land is fertile for the reproduction of wealth via energy production, while on the other hand, it does not represent a significant

benefit to the local populations. For Ahlborg (2018), this contradiction is the result of the unequal social order that generates unequal results of power and produces growing feelings of disappointment and frustration among the actors involved.

In the Northeast Semiarid, the scarcity of rain, accompanied by high temperatures and evapotranspiration, triggers a real competition for water and, consequently, a water crisis is potentially more serious in rural areas. Water deficiency affects the poorest groups, especially small farmers, who face and live with the risk of food insecurity. All these impacts add to the crisis in the availability of clean water in the 21st century, which is seen more as a management problem, as well as technological and financial support, rather than a crisis determined by scarcity and lack (Tundisi, 2010).

In the semiarid region, rainfall irregularity defined policies to mitigate the impacts of drought. Historically, policies prioritized the construction of reservoirs that answered to assistance actions, and permanent and structured interventions. Reservoirs, better known as weir, have changed the landscape and provided productive activities. However, the supply of the rural population, dispersed, and small communities that live far from the springs, which continue to depend on water trucks, which can travel up to 250 km/day, was not resolved (ANA, 2017). (A truck equipped with a large tank, or reservoir, used to transport water <https://www.google.com.br/search?q=Dicion%C3%A1rio>.) This is the solution for locations with chronic scarcity that live with the poor spatial and temporal distribution of water resources (Schroeder and Conti, 2013).

In Brazil, the average water consumption is 153.6 L/inhabitant/day. In 2017, the consumption varied regionally, being discrepant between the Southeast, with 180.3 L/inhabitant/day and the Northeast regions, with 113.6 L/inhabitant/day (ANA, 2018). With the effects credited to climate change on water resources, the per capita water availability is insufficient in the states of Rio Grande do Norte, Paraíba, Pernambuco, Alagoas, and Sergipe. The situation is becoming unsustainable for the populations of these states affected by water stress (Marengo et al., 2011).

With water deficit at least 70% of the year, according to Marengo et al. (2011), increasing scarcity and resource constraints increase water vulnerability and, as a result, socioeconomic conditions deteriorate and may compromise food production in the countryside. In turn, the population becomes impoverished, and their escape to the cities may be inevitable, signifying their uprooting of the rural space, and thus the maintenance of the cycle of poverty in the urban space.

On the other hand, the favorable weather conditions in the region led to the implementation of large agroindustrial complexes for the production of tropical fruits. The main centers are located in the Mossoró region, in the states of Rio Grande do Norte and Ceará, and the region of Petrolina and Juazeiro, in the states of Pernambuco and Bahia. These are irrigated crops that use high technological intensity in the various stages of the production chain and account for the occupation of labor at the poles. Table 1 shows the production data of the main crops in the region for 2017. It is noticed that some products such as cashews, melons, mangoes, and papaya account for >50% of national production. In turn, cashews, melons, mangoes, papayas, grapes, watermelons, and lemons are exported, with important participation in the country's trade balance (Kist et al., 2018).

Considering the significant numbers of agricultural and renewable energy production, especially from solar and wind sources, when confronted with the socio-environmental reality in the Semiarid region, that is, the low social indicators and the environmental weaknesses represented by water scarcity and the permanent threat of desertification, it is clear that the development model put in place requires a strong adjustment in its policies. The abundance expressed in the results of the region's production system, with the production of electricity for large consuming centers through renewable sources, and fruits with the quality demanded by the developed markets, contrast with the reality experienced by the majority of the population that resides in the Semiarid. An enclave effect has thus been constructed, where the benefits help few, but the negative effects and cultural impacts are extensive (Ioris, 2011).

Table 1 Output quantity and exported from the main fruits in Northeastern Brazil in 2017.

<i>Fruit</i>	<i>Output quantity (t)</i>	<i>Share of the national production (%)</i>	<i>Export quantity (t)</i>	<i>Export share in production (%)</i>	<i>Main producing state</i>	<i>State share in export (%)</i>
Cashew	131,906	99%	11,522,688	9%	CE	79%
Melon	514,276	95%	233,299,436	45%	RN	70%
Mango	812,275	75%	167,262,032	21%	BA	50%

The Emergence of Modernization of the Northeastern Semi-arid and the Permanence of Poverty in the Abundance

The images of the Brazilian Northeast are marked by poverty and misery, under the cloak of economic backwardness and climatic conditions present in the conception of drought region, generated by political projects that were thought from superficial propositions. However, this conception denotes the reality of the regional semi-arid space, when its definition disregarded its socio-environmental complexity and considered the regional phenomenon of droughts as the main reason for the Northeast's economic doldrums (de Castro, 1984). As a result, the region received special attention during the first decades of the 20th century, resulting in emergency policies and projects involving, above all, the semi-arid space.

This issue served as the basis for the development of regional development policies, in particular, the creation of the Northeast Development Superintendence (SUDENE), which began to make efforts to boost the economy of stagnant regions and promote their integration with the national territory, resulting in the diversification of economic activities after 1960.

From this decade, with the State's support, the Northeast was the object of investments to meet the new planning model that, on the one hand, modernized it, giving it a new economic dynamism, and on the other, maintaining the traditional structures. of resistance to modernization, as happened in territorial patches of sugarcane, cacao and semi-arid backlands (de Araújo, 2015).

In the context of economic modernization, the developmental industrial model has strengthened the region's link with the country's southeast, and the poles of irrigated agriculture with national and international markets. However, such dynamism has not reached everywhere, leading to large interregional economic imbalances and increasing social inequalities. The coexistence of imbalances and inequalities did not inhibit the actions of the state and monopoly capital, which prioritized the diffusion of new technologies for the use of water, even scarce, to attract investment in the wetter areas of the semi-arid backlands. This region has received large irrigation programs to benefit large economic groups to the detriment of the rural, poor and landless population (de Andrade, 2005).

Thus, the geographically uneven development in the Northeast was consolidated, as it is what matters and guarantees the gains with its location, production, and consumption (Silva et al., 2008). In this way, it was perceived that greater participation of the Northeast in the new globalized economy, embodied as an engine of change, was passively combined with the multinationalized economic and corporate interests that were accelerating (Becker, 2003). Thus, the territory gains new content and imposes new behaviors and, consequently, generates possibilities for production, circulation of inputs, products, money, ideas, information, orders and men (Santos and Silveira, 2006).

New strategies of accumulation and reproduction for the semi-arid region of Brazil, once sentenced to failure, were created with a view to its internationalization. Today, this economic dynamic gives it a new historical configuration. However, the construction of this new regional image did not break with the social drama, remaining in the country as the region with the lowest record of development indicators. Thus, and based on this reason, we consider that globalization, even appropriating or even producing differentiation to expand the inherent mercantile logic, becomes a diffuser of inequalities (da Costa and Porto-Gonçalves, 2006).

Since the threshold of this century, the Northeast has been an alternative for investments in renewable potentials for electric power generation. A new paradigm? From scarcity space to abundance space, the Semi-arid is the jewel of the time, while wind and sun become the adornments lacking to solve the severe problems concentrated mainly in the countryside. Contrary to and frustrating this possibility, water pollution and contamination by pesticides and industrial waste aggravate social and environmental conditions, and circumstances indicate that we are against what needs to be done (UN, 2018).

Semi-arid climatic conditions, water scarcity and the physical nature of soils restrict land use and exploitation, and limit agricultural activities. In this environment, a mass of small farmers end up producing activities with little economic impact or even leaving the field. Contradicting these conditions, this space attracts energy companies that seek intense solar radiation and constant winds of great commercial value for conversion to electricity, confirmed by harnessing the solar and wind energy potential in Fig. 1.

There are 1.5 GWp in solar photovoltaic energy and 12.2 GW in wind energy in installed capacity in the Semi-arid, with the highlight of a total of 17 municipalities distributed in 08 states with photovoltaic solar energy installations, while wind energy is present in 71 municipalities distributed in 06 states.

As for power generation from biomass-fired thermoelectric power plants, a total of 14.8 GW of installed capacity in Brazil was registered on June 2019, using the following sources: sugarcane bagasse; biogas; elephant grass; charcoal; rice husk; ethanol; blast furnace gas from biomass; firewood; black liquor; vegetable oils and forest residues. The Northeast region operates an installed capacity of 1.7 GW from this technology, being 53% of sugarcane bagasse; 41% black liquor; and the remaining 6% from elephant grass biogas, forest residues, and charcoal. However, considering the Semi-arid range, the installed capacity is only 101.12 MW, 94% from sugarcane bagasse, and the remaining forest residues. This discrepancy is justified because most of the sugarcane plantations are located on the coast and, therefore, the use of sugarcane bagasse occurs in this territorial range (ANEEL, 2019).

Water and energy are inextricably linked and fundamental to food production, especially in areas of regional water vulnerability. Water, in particular, is essential to life and the environment, and its scarcity arouses global interest. For Cavalcante Júnior et al. (2019), in the semi-arid region the resources of wind and solar renewables, in addition to the availability of water, have particular characteristics and connect themselves to the scarcity and irregularity of rainfall.

However, such links are not yet unveiled in the Brazilian reality, since renewable energy projects, especially the wind source, prioritize the macroeconomics, marginalizing the local dimension (Riva et al., 2018). A consensus, like renewable energy, as it is being harnessed, is a priority in electricity generation, but it is not intended directly for the welfare of those living in rural areas with which they share the same territory.

Final Considerations

In the Semi-arid Northeast, water requires political, academic and social commitment. It demands full responsibility because the water crisis is everyone's problem and not just a regional one. The crisis and scarcity were determinant for structural changes, but the effects of droughts still fall on a large part of the rural population facing difficulties in agricultural activities (Maciel and Pontes, 2016). Even so, the crisis and the scarcity gain importance to speed up the ways to follow, through new institutional arrangements, including the adoption of renewable energy sources in the regional economy, which must be oriented to overcome social inequalities.

There are reasonable reasons to rethink about the way we produce energy in Brazil or in World. The energy geography shows that there are no limits or borders in the results of the way we treat to the planet considering the persistence of poverty or climates changes. The spatio-temporal characteristics of energy production, chains and use should be revisited under context of scarcity and abundance and this has to be done using many and different scales both for international to regional scale (Brazilian semi-arid).

The Brazilian semi-arid contributes positively to the Brazilian electricity matrix, highlighting the presence of renewable hydroelectric, solar and wind energy sources. The São Francisco River hydroelectric use in the region amounts to 10 GW of installed capacity, where the 09 plants account for 10% of the national hydroelectric generation. Photovoltaic solar energy has 1.53 GW of installed capacity, present in 08 states and 22 municipalities of the Semi-arid, corresponding to 79% of the existing in the Northeast, 73% of the national. And as for wind power, there are 12.2 GW installed in the Semi-arid, present in 71 municipalities and 08 states, which corresponds to 81% of national capacity.

In the hydroelectric case, for the region, the expansion potential is practically exhausted. Photovoltaic solar energy is predominant when considering the national context. However, there is a potential for exploration in the semi-arid region yet to be explored, and there is a prospect of expansion. And as for wind power, there is already an important installed base with potential for further use, as the expected potential for the region has not yet reached 50%. Thus, the semi-arid with 23.7 GW of installed capacity in hydroelectric, solar and wind sources, makes up 20% of the national total for these sources. The current scenario and the future perspective show the region as strategic for the constitution of a strongly renewable national electric matrix.

Thus, despite the water scarcity that characterizes it and negative impacts on socioeconomic and environmental levels, the Brazilian semi-arid region that hosts Caatinga responds to some contemporary economic demands consistently. Irrigated fruit at its exploration centers and the presence of renewable energy exploration, with the prospect of expansion, position the region within the scope of the most recent developments. It should be emphasized that this model that favors accumulation in certain sectors, cannot disseminate this development to its population, which still resents public policies that contemplate it and that try to point out ways for its full development.

Water scarcity in the same space of energy abundance determines that it is necessary to establish a balance in the form of harnessing natural resources, to generate benefits that can make possible the dignified existence of the population that inhabits this space. Achieving this balance requires state bodies responsible for water management to put in place appropriate policies and legal framework to allocate and manage available water resources (GWA, 2003). Hence the importance of following paths for new learning about the limits, potentialities, and unpredictability of long periods of drought. Drought should be addressed as part of climate characterization. However, their intensification may be added as a consequence of climate change. Already its confrontation must be dealt with in the field of public policies, where the role of renewable energies can be crucial in generating local employment, income, and citizenship.

The environmental movement and promotion of renewable sources of energy are meritorious, but when captured by the restricted interests of capital reproduction, it loses its purpose. In this sense, this approach reinforces the idea of the consensus built on renewable energy sources as inducing local development when it is separated from the social dimension.

The sustainability discourse associated with the promotion of renewable sources of energy tends to be an instrument of persuasion and social conviction of technologies when the perspective of the appropriation of gains by the local community is not incorporated. (Chomsky (2013a, 2013b)) states that in more developed societies coercion and force are no longer working tools. In this sense the established power structure seeks instruments of coercion to impose their thinking, ultimately seeking behavior control. In the context of the built consensus, Chomsky (2013a) points out that the image of the world that is presented to society has only a pale relationship with reality.) This issue takes shape in particular in regions of extreme economic and social need, such as the Northeastern Semi-arid. Bauman and Donskis (2014) point out that societies should not fall into adiabaticization, where the established standard model is limited to the consumer-commodity relationship, i.e., technological advancement is not exempt from the ethical and moral issue.

The combination of strategies to reduce inequalities as well as the promotion of renewable technologies can have a considerable impact on reducing the heterogeneities of social conditions, promoting the appropriation of gains by local communities.

Finally, nature has endowed the region with plenty of sun and wind and has deprived it of water and fertile land. This unequal impact requires efforts to link these natural resources through technological progress, which has enabled the development of hydraulic and energy systems. However, the connection between development and technological progress goes *pari passu* with monopoly capital, but still indifferent to the prevailing conditions of poverty and misery of most semi-arid rural families.

Abstract

Uganda has strong opportunity for Climate Smart Energy Technologies (CSET) trade expansion with 89 out of 96 countries in the scope of this article. The contributory cost of technologies to ensuring access to electricity for all Ugandans by 2030 ranges between \$0.63 billion and \$1.24 billion. The assumed level of electricity demand per household in each settlement, is an important factor determining which technology offers the lowest cost. At the lowest consumption levels, most settlements will find that stand-alone systems are the most economical option (with solar PV technology a highly viable option). At this low level of consumption, mini-grid wind technology plays only a minor role. Assuming higher consumption levels implies that mini-grid solar PV becomes an economically attractive option and replaces stand-alone solar PV technologies in many settlements.

Introduction

The United Nations Framework Convention on Climate Change defines climate change as a shift of temperature and/or precipitation that is observed over comparable periods of time, attributed directly or indirectly to human activity, above that caused by natural climate variability (United Nations, 1992). The Intergovernmental Panel on Climate Change (IPCC) finds with 95% certainty that human activity, by increasing concentrations of greenhouse gases in the atmosphere, has been the dominant cause of the observed warming since the mid-20th century. According to a 2014 *Overseas Development Institute (ODI) publication*, the primary sources of emissions are fossil fuel emissions and changes in land use.

To address these drivers of climate change, are climate-smart energy technologies which are an important subset of climate-smart goods and technologies (UNESCAP, 2011). UNESCAP (2011) mentions four categories of climate smart energy technologies; clean coal technologies, wind power, solar technology, and energy-efficient lighting. The World Trade Organization (WTO) provided a list of 153 environmental goods as a result of The Doha Ministerial Declaration. The World Bank identified 43 climate-friendly products that had been derived from the previously submitted WTO 153-product list. In addition, UNESCAP proposed a list of an additional 21 products that appeared on one of the International Centre for Trade and Sustainable Development (ICTSD) lists and also on one of the Asia-Pacific Economic Cooperation (APEC), Organization for Economic Co-operation and Development (OECD) or WTO lists. In total, the list comprises 64 Climate-smart goods and technologies (CSGTs) classified by the Harmonized Commodity Description and Coding System (HS) 2002 codes at the 6-digit level of the Harmonized System.

Technology transfer, the act of conveying knowledge from one organization or sub-unit to another, is necessary if the above technologies and goods are going to adopted broadly. Teece (1977) identified four stages of technology transfer: (1) pre-engineering technological exchanges, (2) transfer of process design and associated process engineering for process innovation; product design and production engineering for product innovation, (3) use of research and development to adapt and troubleshoot the technology, and (4) pre-startup training and process debugging costs.

Most of the previous studies have attempted to answer the question: "Is there any trade opportunity for climate smart energy technologies to mitigate climate change?" For example, the research work includes Anbumozhi et al. (2016); as well as World Bank (2008). Haselip et al. (2011) aim to share different views about enabling frameworks and best practices for technology transfer in the area of climate change. Notable, quantitative analysis using gravity modeling has been widely used to describe trends in trade in climate smart energy technologies, as well as identifying opportunities for expanding trade and investment in climate smart energy technologies. Furthermore, energy system modeling with the integration of geographic information system (GIS) has

been used to help identify the most effective electrification strategy on a geospatial basis. In addition, liberalization and facilitation of trade in climate smart energy technologies is also popularly examined in order to ensure access by all countries as seen in [UNESCAP \(2011\)](#).

Among a number of studies applying the gravity model in international trade, many scholars focus on predicting the trade potentials and examining determinants affecting trade relations, such as [Nguyen and Kalirajan \(2016\)](#). In addition, the gravity model has been extensively used to analyze the effects of common Free Trade Areas (FTAs) using the dummy variables on common borders. Noticeable studies include [Jafari et al. \(2011\)](#); as well as [Binh et al. \(2011\)](#).

Among a number of studies applying the electrification planning methodologies, drawing on geographic information system (GIS) tools, many scholars focus on categorizing zones into areas that are more appropriate for either conventional or renewable technologies based on techno-economic criteria, e.g. [Amador and Domínguez \(2005\)](#) and [Szabó et al. \(2011\)](#) investigated energy solutions in rural Africa.

Uganda Case Study

Uganda's National Development Plan (2010–15) recognized climate change action as crucial for the country to become a competitive, upper middle-income country by 2040 ([Bickersteth, 2015](#)). As part of the review, this case study investigates the transfer potential of climate smart energy technologies to Uganda to answer the main question: "How can climate smart energy technology transfer be fostered to a developing country like Uganda at affordable prices without undermining entrepreneurship and investor confidence, and consequently, innovation and economic welfare?"

The case study demonstrates the gravity model to measure the trade potential of Climate Smart Energy Technologies (CSET) for Uganda. In addition, the geographic information system (GIS) based, Open Source Spatial Electrification Tool (OnSSET), is used to estimate energy demand and the most cost-effective supply option for a particular location.

Methodology

Gravity Model

The gravity model has been used extensively in empirical international trade since it was introduced by [Tinbergen \(1962\)](#), who pointed out that empirically trade between two countries was determined by their relative masses and their distance from each other. The gravity model employed within this study for estimation and analysis purposes is considered as the following equation, in which all continuous variables are expressed in logarithms:

$$\ln T_{ij}^t = a_{ij} + a_1 \ln GDP_i^t + a_2 \ln POP_i^t + a_3 \ln DISTANCE_{ij} + a_4 \ln REER_{ij}^t + a_5 \ln INFR_i^t + a_6 \ln INFR_j^t + a_7 BORDER_{ij} + a_8 TA_{ij} + e_{ij} \quad (1)$$

In which:

$i = 1, 2, \dots, 96$ (trade partner countries); $j = 1$ (Uganda); t implies years from 2007 to 2016.

e_{ij}^t : error term.

T_{ij}^t denotes country (i) trade value in Climate Smart energy technologies with country (j) in year (t).

GDP_i^t and POP_i^t describe the gross domestic product (GDP) and population of country (i) in year (t), respectively.

$DISTANCE_{ij}$ measures the geographic distance between country (i) and country (j). $REER_{ij}^t$ is the real effective exchange rate between country (i) and country (j) in year (t). $INFR_i^t$ and $INFR_j^t$ indicate the quality of infrastructure score index of country (i) and country (j) in year (t), respectively.

$BORDER_{ij}$ is the dummy variable for common border, which take the value of 1 if the two countries share the same border and 0 otherwise.

TA_{ij} represents the dummy variable, which is equal to 1 if country (i) has the trade agreement with Uganda, otherwise 0.

Gravity Model Data

This case study follows [UNESCAP \(2011\)](#), to identify the list of 64 climate-smart goods and technologies (CSGTs) classified by the Harmonized Commodity Description and Coding System. Uganda's trade data on climate smart energy technologies is taken from the UN Comtrade database (<http://comtrade.un.org/>). The countries of consideration are the main trading partners of Uganda for climate smart energy technologies. GDP and population data is taken from the World Bank Development Indicators (<https://data.worldbank.org/>). Data on exchange rates is obtained from the official website of World Bank. Data on distance and borders employed within this study is drawn from the website of Centre d'Etudes Prospectives et d'Informations Internationales (CEPII) at http://www.cepii.fr/CEPII/en/bdd_modele/bdd_modele.asp. The distance is geographic distance between Uganda and its main trading partners. The quality of infrastructure scores of both Uganda and her trading partners are taken from the Global Competitiveness Report released annually by the World Economic Forum. This index covers the quality of the transport and

communications infrastructure network. General infrastructure in the country is ranked for all selected countries in this study, ranging from 1 for underdeveloped to 7 for extensive and efficient ones. Trade agreement participation including both multilateral and bilateral ones is collected from the website of Uganda's Ministry of Trade, Industry and Cooperatives.

Jakab et al. (2001) propose the concept of speed of convergence to calculate potential trade. The average speed of convergence is defined as the average growth rate of potential trade divided by average growth rate of actual trade between the years of observation:

$$\text{Speed of convergence (SC)} = (\text{Average growth rate of potential trade} / \text{average growth rate of actual trade}) \times 100 - 100 \quad (2)$$

Accordingly, we suggest convergence if growth rate of potential trade is lower than that of actual trade and the computed speed of convergence is negative with the divergence in the opposite case. The argument for the prominent efficiency of this method over the point estimated method is that the speed of convergence exploits the dynamic structure of the data during the estimation, which offers a more reliable analysis than the point estimates.

This case study computes trade potential with the help of following formula:

$$\Delta T = \text{Predicted} - \text{Actual trade flows} \quad (3)$$

For our analysis, in particular, we denote convergence if SC and ΔT turn out with the opposite signs, and we posit divergence in the opposite case.

The OnSSET model and its main accompanying steps pursued in this study are summarized in the flow chart below (see Fig. 1).

It is based on the Open Source Spatial Electrification Tool by KTH-dESA (2018). Uganda's Energy Sector GIS Working Group data is used to determine the existing and planned transmission network as well as power plant location. Additional costs are assigned to the electricity grid expansion process based on the topology of the entire country. In order to develop energy demand scenarios, "tiers" of access are incorporated. A mini and small hydro potential dataset is one of several datasets used for this study. Moreover, night-time light datasets are used in combination with the population distribution, the transmission and road network in order to identify the presently electrified populations. In this analysis, the costing of each technology considers the topological characteristics of the country, e.g. areas on higher elevation would indicate an additional investment cost due to higher construction and transportation costs. Likewise, proximity to the road network, land cover, slope gradient and distance from substations affect the initial investment cost. The modular approach (indicated in Fig. 1 above) allows for data sets to simply be replaced when more accurate or updated information is available.

Fig. 1 Framework of OnSSET and principal data sources.

Energy Demand

Geospatial data entailing the administrative boundary of Uganda, population density which is “assigned” to point locations of 1 km by 1 km, hereinafter called settlements, existing infrastructure (transmission lines) and national access to electricity is processed to derive information about the current electrification status of Uganda. Thereafter, the transmission grid is assumed to expand to connect with planned power plants. The population is adjusted to reflect the population projected for 2030 by the Uganda Bureau of Statistics. Population combined with different tiers of electrification leads to future electricity demand scenarios—a crucial input to the cost-optimal allocation of electrification options. Each tier represents different levels of electricity services provided, starting from basic lighting to services that provide comfort, such as air conditioning as captured in **Table 1** below.

The various tiers are assessed for all given grid points in order to capture different specificities of energy demand levels per region. In reality, significant income differences across the country would imply different energy demand levels and all five tiers are likely to co-exist in the country.

Assigning Costs

The energy options analyzed include categories of renewables among them mini-grid systems and stand-alone systems. For every GIS cell, the levelized cost of generating electricity (LCOE) of these options are evaluated. The resulting LCOE information is fed into the GIS model to determine the most economical option for each grid cell given its geospatial characteristics. In this analysis, diesel prices are considered in order to assess how increasing oil prices influence the least cost energy mix.

Results and Discussion

The independent variables (GDP_i^t , $POPI_i^t$, $REER_{ij}^t$, $INFR_i^t$, $INFR_{ij}^t$) explain approximately 17% variations of trade values of Climate Smart Energy Technologies between Uganda and its 96 trading partners. This value is due to the omission of “DISTANCE_{ij}”, “BORDER” and “TA” variables because of collinearity (**Table 2**).

Uganda’s trade of Climate Smart Energy Technologies is positively correlated with the economic size of its trading partners. Larger economies tend to have a higher supply of exporting Climate Smart Energy Technologies to Uganda. Also, the increase in GDP reveals that these countries are able to produce larger amounts of Climate Smart Energy Technologies for export to Uganda. This positive relation is in line with higher incomes allowing for more resources being available for cleaner technologies, as well as higher Research and Development for clean technologies. Accordingly, larger economies mean higher promotion of cleaner technology development, and a better marketing system for supplying those technologies.

Foreign Labor force, positively influences trade in Climate Smart Energy Technologies. This positive correlation can be explained by the fact that as population grows, the trading partners may increase technological output for export while utilizing more skilled and/or cheaper labor. Over the years, the challenges in transportation have affected the transportation cost and hindered the inflow of technologies to Uganda.

The exchange rate variable, linked to the impacts of price variations due to exchange rate volatility on trade flows of Climate Smart Energy Technologies, is negatively associated with technology transfer. In particular, the appreciation of the Uganda Shilling against the currencies of trading partners results in an increase in import value of Climate Smart Energy Technologies to Uganda. The negative impact on the trade value can be explained by the fact that Uganda’s imports of Climate Smart Energy Technologies are capital-intensive climate components. As a result, an increase in exchange rate leads to a decrease in the trade value of climate smart energy technologies.

An increase by 1 unit in exchange rate means the Uganda Shilling appreciation would reduce trade in Climate Smart Energy Technologies by Uganda to the tune of 0.08 units. The estimated coefficient value also reveals a negative long run relationship between the real effective exchange rate and trade value. Therefore, the management of the exchange rate plays a major role in promoting trade of Climate Smart Energy Technologies especially with regard to the fact that Uganda is a net importer of those

Table 1 Mapping of tiers of electricity to indicative services.

Access level	Tier 1	Tier 2	Tier 3	Tier 4	Tier 5
Indicative appliances powered	Task lighting + phone charging or radio	Tier 1 + general lighting + air circulation + television	Tier 2 + light appliances	Tier 3 + medium or continuous appliances (i.e. water heating, ironing, water pumping, rice cooking, micro wave)	Tier 4 + heavy or continuous appliances
Consumption per capita per year for a certain efficiency level (kWh)	8	44	160	423	598

goods. The two variables reflecting the overall quality of infrastructure of Uganda and its trading partners are both found to have negative coefficients as per the result of the model.

The overall infrastructure scores included in the model reflect the modes of transport—including high-quality roads, railroads, ports, and air transport—which enable entrepreneurs to get their goods and services to market in a secure and timely manner and facilitate the movement of workers to the most suitable jobs.

Estimation indicates that the quality of infrastructure of both Uganda and her trading partners are important determinants of Uganda's trade performance in Climate Smart Energy Technologies. In particular, a unit improvement in the scores of Uganda and 89 countries leads to a 2.06 and 0.38 unit decrease respectively in the trade value of Climate Smart Energy Technologies to Uganda. Also, it is clear that the improvement of the infrastructure index of Uganda's trading partners has a relatively larger impact on the trade value compared to that of Uganda. Extensive and efficient infrastructure is critical for ensuring the effective functioning of the economy. Additionally, a well-developed infrastructure system is essential for attracting foreign direct investment in cleaner technologies and production which are crucial for promoting trade of climate smart energy technologies in Uganda. Therefore, a better infrastructure is not only strongly associated with the expansion of Climate Smart Energy technology trade but also with Uganda's trade in other commodities and economic growth in general.

According to [UNESCAP \(2011\)](#), among the most important barriers to climate-smart foreign direct investment are technical/infrastructure (including grid-related) barriers.

Trade potential of Climate Smart Energy Technologies for Uganda.

Considering only statistically significant coefficients, the estimated trade of Climate Smart Energy Technologies for Uganda is as follows:

$$\text{LnT}_{ijt} = -115.438 + 0.191 \times \text{LnGDP}_{it} + 7.246 \times \text{lnPOP}_{it} - 0.084 \times \text{lnREER}_{ijt} - 0.377 \times \text{lnINFR}_{it} - 2.059 \times \text{INFR}_{it} \quad (4)$$

The regression results from Eq. (2) are employed to estimate the speed of convergence (SC) and the difference between potential and actual trade value of Climate Smart Energy Technologies (ΔT). The calculation of trade potential of Climate Smart Energy Technologies for Uganda is presented in Table 3 below.

The bilateral trade situations in Climate Smart Energy Technologies between Uganda and its 96 trading partners are divided into two separate groups, i.e. convergence and divergence. Trade opportunity of Climate Smart Energy Technologies denoted by the convergence situation implies that there is a scope to increase Uganda's trade value of products with its particular partners.

Considering both Speed of Convergence (SC) and trade potential (ΔT) for each particular market, this study is able to identify that Uganda had convergence with 89 out of 96 countries in the scope of the research for this article. In this regard, Uganda has not exploited full potentials in trading of Climate Smart Energy Technologies with 89 countries. In other words, there is a large scope for trade expansion between Uganda and those countries in the next period.

Geospatial Electrification Analysis for Renewable Energy Technology

In total, four scenarios focusing on wind power and solar photovoltaic (PV) technologies were created for Uganda using OnSSET. These scenarios clearly show that the assumed level of electricity demand per household in the settlements is an important factor determining which renewable energy technology offers the lowest cost (Figs. 2–5).

At the low consumption level, most settlements will find that stand-alone systems are the most economical option (i.e. solar PV technology). At this low level of consumption, mini-grids, more so wind technology mini-grids plays only a minor role. A mini-grid is a set of small-scale electricity generators and possibly energy storage systems interconnected to a distribution network that supplies electricity to a small, localized group of customers and operates independently from the national transmission grid. Mini-grids range in a size from a few kilowatts up to 10 MW (Introduction to Mini-grids, n.d.). Higher energy consumption levels imply that mini-grids more so solar photo voltaic technology mini-grids become an economically attractive option and replace stand-alone solar photo voltaic technologies in many settlements hence increasing their overall contribution to achieving access to electricity for all Ugandans by the year 2030.

The contributory cost of the solar photo voltaic and wind renewable technologies in ensuring access to electricity for all Ugandans by 2030, ranges between \$0.63 billion and \$1.24 billion by the year 2030. The lower a household's electricity consumption, the lower the overall investment needed to achieve access to electricity for all by the year 2030 though this can peak at a certain high consumption (as captured in Fig. 5) and thereafter dip.

Considering the solar PV and wind renewable energy technologies, the lowest-cost investment ticket for achieving access to electricity for all Ugandans by the year 2030 corresponds to scenario 4 below where consumption is assumed to be at tier 5 for urban, and tier 4 for rural. The highest investment cost on renewable energy technologies corresponds to the household consumption (tier 4 for urban, and tier 3 for rural) in scenario 3 below. When the consumption levels are low, the considered renewable energy sources will be used to provide electricity to an average of 16% of the population. However, increasing the energy consumption level to tier 5 for urban and tier 4 for rural (scenario 3) reduces the average contribution of the considered renewable sources to 10% of the population (Figs. 6–9).

Case Study Conclusion

The case study shows there is huge room for trade expansion with 89 out of 96 trading partners in the scope of this article. There appears to be a great urgency for Uganda to pursue consumption of Climate Smart Energy Technologies which not only will contribute to economic growth but also will reduce the impacts of climate change in Uganda. Taking advantage of opportunities at hand will require several fundamental policy interventions.

Conclusion

Many pertinent considerations arise for siting a renewable energy resource. For example, does the site allow for interconnection to the electrical grid and transmission of the energy generated? How suitable is the land where the facility will be physically located? What impacts should be expected on surrounding land, water, and wildlife? How will the facility affect the local community? A wide range of legitimate concerns give rise to local opposition to new energy infrastructure of whatever kind, from the local environmental and health effects of a facility, to environmental justice in site selection, to perceived impacts on surrounding property values and esthetic considerations. The answers to these questions are inevitably both resource and site specific.

Despite work in technology transfer, there remains difficulty in developing countries to recruit individuals that understand and can interpret the science of climate variability. The ability to understand and effectively communicate potential future climate-based scenarios to decision makers are thus critical success factors for adaptation and mitigation strategies (Noe et al., 2007). This capacity resides with human resources. It is impossible to adapt to climate change without linking the process up with people who take the decision that impairs or makes the environment.

To train people for climate change adaptation and mitigation is critical to the success of the campaign on environmental sustainability with climate change. Although the training should be goal-driven, the output is largely determined by the input of the trainee. Awareness and educational capacity reflect on the expected input of the trainee. Therefore, one should be exposed to challenges and allowed a robust level of latitude to contribute toward dealing with the problems. The robustness makes for creativity. However, the capacity building approach to climate change adaptation and mitigation has a long gestation period as a setback.

Legislation alone cannot offer all the solutions of climate change adaptation and mitigation. There is need to focus on the attitude and commitment of people who operate the policies. The future challenge for the educational and energy technology policies perhaps is implementation. The more the implementation is devoid of corrupt tendency the farther the project of advancing climate change resilience will be on its road to success.

Abstract

This article represents a status assessment of the Mariana Islands developed system, including the current status, stressors, and future viability. Developed systems within the Marianas Archipelago exist where there are human populations, primarily focused on the coasts of Guam, Saipan, Rota, and Tinian Islands. The quality of the developed system is largely composed of a mixture of nonnative vegetation types, and predominantly nonnative wildlife. Our assessment of the developed system viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resiliency. The main stressors to developed systems are effects of climate change, additional development, typhoons, pollution and invasive species. Ongoing conservation efforts are helping to protect plants and wildlife within developed systems, and the conservation depends largely on combined efforts of State, Federal, multiagency organizations, nonprofit organizations, and the voluntary support of private landowners. The Marianas developed system represents a unique land use type, whose composition is dynamic across its range. Due to growing human population numbers, the developed system is likely to decrease in size over the coming years, as development increases. Projections for the persistence of developed systems in the Marianas largely depends on the conservation actions taken, which should be implemented to safeguard pockets of biodiversity found within these systems.

Introduction

The geography, geology, climate, hydrology and descriptions of the islands in the Marianas archipelago are described in the Physical Geography of the Mariana Archipelago by Harrington included in this work. However, what the above factors lack is how land use and land cover change also reflect the role of human population density and land use intensity. Across the Marianas archipelago increasing population and land use intensity has resulted in a shift in the landscape towards dense settlement and populated anthromes (Ellis et al., 2010).

This document provides an overview of the developed system in the Mariana Islands Archipelago (Marianas) and describes the ecological factors that have influenced this system over time and into the future. It provides an assessment of the system, its current status, stressors, conservation efforts, and future viability. Developed systems can occur in any location on the islands but, are primarily located in coastal areas where the majority of the human population resides. This system type displays varying amounts

of vegetation, impermeable surfaces (e.g., roads, parking lots, buildings), and permeable surfaces, and can range from small farms to homes, and dense commercial development. Developed systems are generally dominated by nonnative and, often, invasive species. The vegetation is actively managed and generally maintained through planting, irrigation/artificial watering, and/or mowing.

The Marianas archipelago consists of the island of Guam in the south, and the remaining islands stretching northward in the archipelago are the Commonwealth of the Northern Mariana Islands (CNMI). The island of Guam is an unincorporated territory of the United States and the CNMI is an insular area and commonwealth of the United States. The majority of the human population currently resides on the southern islands of Guam, Rota, Tinian, and Saipan (Fig. 1A–C).

The amount of developed area is associated with human populations found on each of the islands across the Marianas. Due to the population sizes, Guam and Saipan have the largest amount of developed area both, in absolute size, and relative to land mass, followed by Rota and Tinian (Figs. 1 and 2). The remaining islands have less than one acre of developed area. The developed system is defined as the ecological area within developed areas, and is comprised of planted landscape, farmland and agricultural areas, and remnant grass and forest patches distributed throughout the landscape. The developed system is defined as containing impermeable man-made surfaces, landscaped areas, active cropland areas, roads, towns, parks, golf courses, airstrips, quarries, and military facilities, being highly influenced by ongoing human activities, typically with < 10% vegetative cover. While much of the developed system is comprised of nonnative vegetation, small remnant areas of native vegetation may exist. Our assessment of developed system viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resilience.

Stressors to developed systems reduce the quantity and quality of vegetation, but also may result in an expansion of the system, especially to the currently unoccupied islands. Naturally occurring stressors including typhoons and drought have and will continue to impact the developed systems. Remnant forest areas that have not been developed, are dispersed throughout the landscape. There are also many planted landscapes that are primarily comprised of nonnative vegetation. The primary stressor in the developed system is the construction of impermeable surfaces and buildings which reduce the quantity of vegetation. The conservation of these systems depends on combined efforts of Territory, Commonwealth, Federal, multiagency organizations, private landowners, and passive/social management through policies, laws, and land protections.

We developed four plausible future scenarios, each differing in their levels of natural resource management, to evaluate the status of developed systems into the future. The future scenarios are based on analyses of land cover changes documented in geospatial layers for the time period until 2035. Scenario one is essentially “status quo” continuing for the foreseeable future, which means we envision no change in the three conservation management parameters: conservation values, conservation and biosecurity-related laws, and Territorial/civic planning for development to the year 2035. Scenario two is essentially “status quo” with minor improvements in the three conservation management parameters. In scenario three, all actions of conserving native habitats and their ecosystems are set aside in deference of economic development, and small areas are maintained as conservation parcels. Scenario four envisions a foreseeable future with substantial declines in the three conservation management parameters. Scenario four

represents an overt and robust, active, ongoing conservation effort (seeking moderate to major resources) to (a) identify and prioritize, with partners and stakeholders, the habitats and ecosystems needed for conservation, and (b) actively restore and expand these habitats and ecosystems. Scenario four envisions a foreseeable future with substantial improvement to the three conservation management parameters.

Developed System Description

The vegetation included in developed systems may consist of a wide variety of trees, shrubs, grasses and other vegetation that is primarily nonnative. This vegetation is present in urban or residential areas that are generally adjacent to impervious surfaces and trail corridors, grown in spaces beside houses and buildings and as part of landscaped, open space areas. Developed systems also include actively managed cropland and fields that are generally maintained through planting, irrigation or mowing such as golf courses and landscaped businesses and residences.

In addition to natural rainfall patterns, vegetation in developed systems is often highly supplemented by artificial irrigation. Both rainfall and artificial watering have the potential to increase runoff and ponding areas along impervious surfaces throughout

Fig. 2 Land cover types within developed systems across the Marianas on the islands of Guam, Rota, Saipan and Tinian (Reeves and Amidon, 2018).

developed and urban areas. The amount of water available and retained can vary based on the substratum. The developed system has the potential to exist in any type of substratum across the volcanic or limestone areas of the archipelago. Some examples of these soil types include shallow, well drained, moderately rapidly permeable soils in limestone whereas other volcanic soils can be very deep, somewhat poorly drained, moderately slowly permeable soil with moderate to very high water holding capacity (College of Natural and Applied Sciences (CNAS), 2018).

Categories of Developed Systems

Developed systems include the following four landcover types: (1) developed, (2) developed vegetation, (3) bare soil/gravel/rock, and (4) cropland (Table 1). Developed areas include buildings and impervious surfaces (Amidon et al., 2017). Developed vegetation includes manicured lawns, golf courses, parks, and ornamental vegetation. Bare soil and gravel habitats are primarily comprised of quarries and consolidated formations. Croplands include all irrigated plots of land that were cleared for the production of various crops, as well as fallow agriculture fields. Vegetation in developed systems includes a wide variety of species including various well-pruned native and nonnative trees, grasses, and shrubs. Since the majority of vegetation in this system was intentionally planted either for agricultural or ornamental purposes, developed systems tend to be dominated by nonnative species.

Vegetation Composition and Biodiversity

Cropland areas within developed systems may be limited to one vegetation type as a commercial crop or small family farms with a variety of crops including vegetables, melons, root crops, fruits, nuts, coconuts, and nursery crops. Many of these crop types are cultivated in lateritic soils on Guam, which are rich in iron oxide and derived from a wide variety of rocks weathering under strongly oxidizing and leaching conditions (Moore and McMakin, 1979). These various types of agriculture are not necessarily represented by consistency in structure since production on small family farms varies widely. The most common types of crops grown in cultivated lands are tomatoes, bananas, sorghum, watermelons, green onions, eggplants, and cucumbers (United States Department of Agriculture (USDA), 2006; Wiles et al., 1990). The warm year-round climate in the Marianas combined with high levels of humidity, make these islands hospitable for a number of native and nonnative plant species. For example, the island of Guam is home to over 600 species of vascular plants, and more than 100 different tree species (United States Department of Agriculture (USDA), 2006).

The vegetation composition of developed systems usually ranges from barren areas to vegetated areas, and may be very low in species diversity, with limited canopy cover, if any (GIS GAP, <https://gapanalysis.usgs.gov/gaplandcover/data/>). In addition, species composition changes in urban environments such that the number of nonnative species increases and native species decreases (McKinney, 2002). The species most affected by invasion of nonnative species are the endemic species, likely because they have evolved on islands and show the least competitive ability (Lee, 1974). Palm trees are commonly cultivated in urban areas, due to their relatively low maintenance and small footprint. Grassed areas such as golf courses and soccer fields are also common in developed areas. Due to developed areas resulting from modern human modification, no prehuman condition exists for developed system areas.

Table 1 Developed system categories (Amidon et al., 2017).

Category	Description
Developed	All buildings (concrete and other materials), paved surfaces, and roads. Gravel roads are generally included in this category as well.
Developed vegetation	Includes lawns and mowed areas as well as ornamental and shade trees and shrubs. Parks, golf courses, and residential open spaces are also included.
Bare soil/gravel/rock	All consolidated formations such as rock and quarries.
Cropland	All agriculture fields and sites planted for agriculture, including recently cleared or planted lands, as well as managed fallow fields. Agricultural trees and shrubs planted in rows are also included.

Vegetation in developed systems is primarily planted and maintained with human influence. However, there are a variety of sources of natural recruitment and dispersal. Pockets of remnant forest exist in urban areas, providing a source of seeds. Wind plays a major role in spreading prolific seeds of invasive plants throughout the islands, as does wildlife that traverses the area. Invasive plants such as ivy gourd (*Coccinia grandis*) are presumably spread throughout the developed systems by birds and invasive mammals.

Fauna found in developed systems may consist of many of the same species found in more natural areas (birds, insects, bats) but are limited by availability of foraging and nesting resources and by the effects of habitat fragmentation in the large spaces created between individuals and populations. For example, roads favor species with expanded dispersal abilities in disturbed habitats at the expense of species with limited mobility. Research has shown that development and urbanization has the ability to alter ecological processes (Moll et al., 2019). Habitat fragmentation may pose barriers to animal movement, while increasing the connectivity of disturbed sites promoting the spread of nonnative weeds, pests, and pathogens (Noss et al., 2006). The fauna in developed systems within the Marianas consists primarily of nonnative mammals, including pigs (*Sus scrofa*), deer (*Rusa marianna*), shrews (*Suncus murinus*), snakes (*Boiga irregularis*), domestic cats (*Felis catus*), and dogs (*Canis lupus familiaris*), and rats (*Rattus* spp.) (Wiles et al., 1990), and birds, including Eurasian tree sparrow (*Passer montanus*), black drongo (*Dicrurus macrocercus*), and Philippine turtle-dove (*Streptopelia bitorquata*; Engbring and Ramsey, 1984; Engbring et al., 1986). Among the plant species recommended by the CNMI government for disturbed areas in developed systems, are sumac (*Aidia cochinchinensis*), Niyoron (*Cordia subcordata*), Alum (*Melanolepis multiglandulosa* var. *glabrata*), Lada (*Morinda citrifolia*), Amahadyan (*Pipturus argenteus*), and Ahgoa (*Premna obtusifolia*) (Zarones, 2014).

Current Condition

There is a wide range of development across the Marianas which is primarily correlated with human population. Guam and Saipan are the most populated islands across the island chain and thus have the largest percentage (21% and 23% respectively) of developed area (Figs. 1 and 2; Tables 2 and 3) relative to their size. On Guam developed areas are largely concentrated in the northern

Table 2 Amount of developed areas in the Marianas represented by absolute area per island (acres), percentage of developed area relative to island size and percentage of developed area relative to the entire archipelago (Reeves and Amidon, 2018).

Island	Categories	Area (Acres)	Area (% of Island)	Area (% of Archipelago)

portion of the island, while on Saipan developed areas are concentrated on the southern portion of the island. The islands of Rota and Tinian are much less developed with approximately 5–6% developed habitat on each island (**Table 2**). On Rota the developed area is largely limited to Songsong and Sinapalu, and on Tinian development is limited to San Jose. Development, as a result of population increases, has led to pockets of dense tree vegetation in some urban areas, open grassy areas in parks and yards, and numerous palm trees and shrubs along coastal areas. Agriculture makes up <1% of total island area on any of the Marianas (**Table 2**).

System Viability

Systems sustain their existence through resiliency, redundancy, and representation. The viability of developed systems depends on maintaining multiple, distributed system types (redundant) of sufficient quality and size (resilient) with species richness and genetic range (representative) to survive across its ecological range over time. Representative systems are those not restricted to particular locations but are scattered throughout the islands. Resilience is defined as the amount of disturbance that the system can absorb without a lasting change in structure and composition ([Holling, 1973](#); [Carpenter et al., 2001](#)). Redundancy refers to the extent and range of a system across a given landscape, and redundancy of multiple resilient systems can decrease the risk of loss. Developed system disturbances include forces such as typhoons and sea level rise, as well as anthropogenic stressors. Constrained or limited areas, with less representation across the islands, are less resilient to catastrophic events that might otherwise have a relatively minor impact on widely-distributed systems ([Stacey and Taper, 1992](#)).

Stressors

Development

Economic development and associated construction has, and continues to impact, the vegetation within developed systems across the Marianas. The construction of buildings and facilities associated with public infrastructure (e.g., fresh water, sewage treatment, etc.) have the potential to convert developed vegetation, bare soil, and croplands to developed impervious surfaces and structures. Development across the Marianas is primarily correlated with human population size. Developed land areas are currently most prevalent in the southern, more populated islands whose local economies depend on construction and real estate, both privately and associated with the US military ([ICF International, 2009](#); [PEGS, 2018](#)). At least a third of the island of Guam is occupied by the United States military, which includes a variety of land use types including many developed and developed vegetation areas ([Owen, 2010](#)). The military buildup on both Guam and Tinian also increases the likelihood of introducing invasive species, and the

development of additional land areas throughout the Marianas (Marler, 2013). Creating more developed habitat and importing of equipment increases the likelihood of invasive species being introduced, or spreading among islands in the archipelago. Brown tree snakes (*Boiga irregularis*) were introduced to Guam around 1949 as a result of movement of military assets among islands, and continue to have devastating long-term effects on ecosystems and biological composition on the island (Rodda and Savidge, 2007). A loss of pollinators due to brown tree snake predation, has the ability to affect the resiliency and representation of developed vegetation across Guam.

Invasive Species

Many invasive species are established in the Marianas and impact both developed systems, as well as the organisms that utilize the developed vegetation within these systems (Table 4). Urban areas are hotspots for biological invasions, and while additional invasive species may be present, their range and effects have not yet been fully investigated. Many common invasive plants (e.g., *Bidens alba* and *Antigonon leptopus*) thrive in developed habitats across the Marianas because they can survive harsh urban climates, while collecting water from impervious surfaces. Brown tree snakes are prevalent throughout the developed habitats of Guam, and their invasion has led to the near extirpation of a number of native bird, bat, and invertebrate species (Rodda and Savidge, 2007). The Coconut Rhinoceros Beetle (CRB) (*Oryctes rhinoceros*) has had devastating effects on coconut palm trees (*Cocos nucifera*) in developed areas on Guam and Rota, and was likely introduced to Guam with construction materials arriving from Asia (USDA, 2008). Their persistence in the environment may have been driven by the absence of insectivorous birds and mammals, as a result of their predation by brown tree snakes (Moore et al., 2015). The near extirpation of insectivorous birds on the island of Guam has led to a disproportionate number of spiders, with an average of 18.37 spider webs per 10 m on Guam, compared to 0.45 webs per 10 m on nearby developed islands with birds (Rodgers et al., 2012). Invasive ungulates such as pigs and goats graze many islands in the Marianas archipelago, including unfenced croplands in developed systems. They have a notable effect on the abundance and diversity of native plant species within these areas. Their eradication from the islands of Sarigan and Anatahan led to an increase in tree species richness and density, with a composition changing towards a more native and diverse ecosystem (Kessler, 2011). Following ungulate removal, open grass areas were filled with saplings and small trees, leading to 100% ground cover and dense closed canopy. The overall density of tree species increase from 1.48 trees/100 m² to 13.70 trees/100 m² in just 7 years.

Typhoons

The Marianas lie in a region with a high propensity for tropical cyclones (aka Pacific Typhoon Belt) and are therefore, regularly exposed to typhoons. Typhoons cause a variety of impacts to the environment including pruned or downed vegetation from intense wind, defoliation, heavy rain, flooding, and saltwater inundation in low-lying areas (Kerr, 2000). Mortality of any vegetation across

Table 4 Primary invasive species in the Marianas developed systems.

Common name(s)	Scientific name(s)	Primary species affected	How invasive affects the system	Where present	References
Coconut rhinoceros beetle (CRB)	<i>Oryctes rhinoceros</i>	Coconut palms	Loss of vegetation	Guam, Rota	Marshall and Moore (2016)
Invasive ungulates (goats, pigs, Philippine deer)	<i>Capra hircus</i> , <i>Sus scrofa</i> , <i>Rusa marianna</i>	Native vegetation	Soil disruption, increased sedimentation input, compete with native species, deplete natural resources	Guam, Aguiguan, Tinian, Rota, Anatahan, Pagan, Agrigan	Liske-Clark (2015) and Wiles et al. (1990)
Rodents (roof rats, Polynesian rats, Norway rats)	<i>Rattus rattus</i> , <i>Rattus exulans</i> , <i>Rattus norvegicus</i>	Native vegetation, prey on native and nonnative fauna, including birds.	Prevent tree regrowth, damage to crops, compete with forest birds for seeds	All Islands	U.S. Fish and Wildlife Service (USFWS) (2007), Liske-Clark (2015), and Wiles et al. (1990)
Pests (little fire ant, white flies, aphids)	<i>Wasmannia auropunctata</i> , <i>Trialeurodes vaporariorum</i> , <i>Aphis</i> spp.	Agricultural crops and some forestry trees, native vegetation.	Reducing plant vigor	Guam, Rota, Saipan and Tinian	Smith (2004)
Brown tree snake	<i>Boiga irregularis</i>	Birds, bats, lizards, pets	Extirpation of most birds, loss of forest trees due to absence of seed dispersers and pollinators	Guam, Saipan	Rodda and Savidge (2007)

the islands due to a typhoon reduces the quality and resilience of vegetation in developed systems. Typhoons also damage infrastructure and buildings throughout the developed system. Damage from typhoons can open areas for more intense development causing the loss of open space developed vegetation and cropland areas. Additionally, emergency response to typhoons increases the risk of spreading invasive species. Typhoons have the ability to disrupt ongoing conservation efforts to protect endangered species such as the Mariana crow (aka, *Corvus kubaryi*), as was evident when Typhoon Mangkhut, a powerful category 2 storm, hit the island of Rota in September of 2018. The typhoon coincided with the reproductive season for the crow, and severely disrupted the habitat and recovery progress for that species (San Diego Zoo, 2018). In October of 2018 Tinian and Saipan were hit by an extremely powerful category 5 storm, super Typhoon Yutu, which caused widespread damage across the Marianas. The majority of developed structures on Tinian were destroyed, and much of the low-lying vegetation on the island was shredded or uprooted by powerful winds measuring up to 180 mph (295 km/h) (National Hurricane Center (NHC); Hurricane Research Division; Atlantic Oceanographic and Meteorological Laboratory, 2018). The destruction of developed vegetation subunits, which are already fragmented as a result of development, decrease the redundancy and representation of system. The destruction of developed structures and fragmented forest areas may lead to additional development as a result of land being denuded, decreasing the resiliency of the system. Super Typhoon Yutu devastated much of Tinian, including habitat for the Tinian monarch (*Monarcha takatsukasae*), an endemic bird that was removed from the federal list of endangered and threatened wildlife in 2004 (USFWS, 2004). An analysis of vegetation on the island of Tinian following Yutu showed that it caused severe damage and defoliation of vegetation, in habitats utilized by the Tinian monarch (Amidon et al., 2018). The frequency and severity of typhoons in the Marianas are expected to increase as the effects of climate change continue to manifest (Holland and Bruyere, 2014).

Climate Change

According to the Intergovernmental Panel on Climate Change (IPCC), human activities have caused a 1°C increase in temperature above preindustrial levels, and if the current rate of warming remains constant, we could reach an increase of 1.5°C by the year 2030 (IPCC, 2018). Both the size and intensity of large-scale storms are expected to increase in coming years, and recent data demonstrates category 4 and 5 hurricanes have increased at a rate of 25–30% per °C increase in global warming (Holland and Bruyere, 2014). Additionally, ocean warming is causing an increase in recurrent regional coral bleaching events, which have increased fivefold in the last 35 years (Hughes et al., 2018). Combined with ocean acidification, these more frequent bleaching events are expected intensify and lead to mass coral bleaching events, disease, and coral mortality (Hoegh-Guldberg et al., 2007). A decline in coral reef cover is expected to impact fisheries and tourism, and increase bioerosion, leading to a decrease in coastal protection. A decrease in coastal protection combined with sea level rise could lead to erosion of the shoreline, particularly in developed coastal areas. The intrusion of saltwater into the freshwater aquifer as a result of sea level rise may lead to the contamination of resources used to sustain vegetation, resulting in habitat migration and a possible disruption in ecological services (Craft et al., 2008). Variation in temperature has the potential to alter key biological processes such as metabolism and reproduction, potentially altering the biological composition of habitats (Stenson et al., 2002).

Wildfires

A growing threat to developed areas in the Marianas is destruction of habitat due to wildfires. Intentionally set wildfires are common, particularly during on Guam during the dry season (January–June). Many of the intentionally set fires adjacent to developed system or in developed vegetation are the result of hunters attempting to drive invasive ungulates out into the open, where they can be easily pursued. Recent data suggests that the creation and expansion of savannas is a direct result of human wildfire activity, and that this has facilitated the spread of invasive species across southern Guam (Athens and Ward, 2004). Between 1979 and 2000 there were an average of 730 fires per year on Guam, which burned a total of 1942 ha (4800 acres), or 4% of the total land area (Minton, 2006). While the wildfires themselves may not occur within the developed system, the denuding of vegetation can lead to erosion and sediment runoff, which can impact coastal, stream, and urban areas within the developed system. The expansion of development into areas burned by wildfires puts developed areas and developed vegetation at risk for future wildfire events.

Point Source and Nonpoint Source Pollution

One aspect of the developed system is the increase in abundance of impervious surfaces, as well as the channelization of waterways, which act as conduits for the movement of pollutants in the environment. Point source pollution is any single identifiable source from which pollutants are discharged, such as large farm outfalls and sewage pipes (Environmental Protection Agency (EPA), 2005). Nonpoint source pollution is the collective result of runoff from multiple sources, both large and small. Examples of nonpoint source pollution includes dirt from construction sites, oil from parking lots, residual pesticides, and septic tank leaching. Pesticide and herbicide use is among the highest in developed systems compared to other system types based on heavy cultivation and agricultural use. There have been demonstrated negative effects to arthropod communities as a result of pesticide runoff, at both the lethal and sublethal levels (Stark and Banks, 2003). Honeybees are an important pollinator of many plant species, and exposure to neonicotinoid pesticides decreases both foraging success and survival, leading to colony failure (Henry et al., 2012). Sublethal effects associated with some pesticides has a negative effect on immune responses, and increases oxidative stress for arthropods

(James and Xu, 2012). Impervious surfaces in developed systems increase the amount of water transported to waterways, and channelized waterways act as conduits for pollutants, which can have deleterious effects on nearshore marine animals and ecosystems (Richmond et al., 2018, 2019).

Conservation Efforts

There are various groups engaged in on-the-ground management of invasive species or loss of vegetation. Management activities are coordinated through cooperative efforts of territorial agencies, Federal agencies, watershed partnerships, private organizations, and individual landowners and passive/social management of developed systems through policies, laws, and land protections.

Invasive Species Management and Control Activities

In general, terrestrial invasive species on small oceanic islands establish and impact most developed system categories. It is often more practical to apply biosecurity and management efforts across the island rather than attempting to focus efforts on specific systems. The level of specificity applied to any control and management effort, however, will vary by location, species, and the suite of associated impacts anticipated or occurring. One factor that may be utilized in developed systems is the potential for rapid detection of invasive species, due to the presence of people in these areas. Several invasive species management programs are reliant upon public engagement and education, in order to detect new invasive species, and their impacts in developed systems. Successful public awareness and citizen science campaigns include the CNMI Brown Bree Snake Interdiction Program to prevent the spread of brown tree snakes, as well as the Humatak Project, a program that protects watersheds by tackling bioerosion issues caused by invasive ungulates (Shelton and Richmond, 2016; Richmond et al., 2019).

Prevention of invasive species through biosecurity (e.g., the management of the risks to animal, plant, human, and environmental health posed by pests and diseases) measures is essential in limiting risk to habitats and species of the Marianas, and preventing the spread of invasive species throughout the islands. Both the CNMI and Guam have biosecurity mechanisms as part of their overall seaport and airport programs. The University of Guam and the Northern Marianas College provide research and extension services to support invasive species management. Activities include CRB monitoring, management, and research programs. Similarly, both the CNMI and Guam have government offices and staff that support management of various established pest species and provide extensive natural resource management, conservation, and restoration efforts.

Local and Federal Management

In Guam, public law 25-152 was put in place to ensure all development projects are reviewed by the local environmental protection agencies and do not result in negative impacts to the human environment. This regulation allows for the Guam Department of Agriculture, Division of Aquatic and Wildlife Resources to review all development projects which will involve the clearing of habitat prior to the start of project activities to ensure that there are no negative impacts to protected species, and to reduce impacts from soil erosion. The Northern Mariana Islands Administrative Code Chapter 65-30, § 65-30-101 details the permit requirements for any land clearing activities. This mechanism was put in place to ensure no unauthorized clearing of habitat occurs in the CNMI. The US Fish and Wildlife Service (USFWS) administers the Endangered Species Act, and consults on federally funded projects in the Marianas to conserve federally listed species and designated critical habitat. The Sikes Act was originally passed in 1960 to direct the US Department of Defense (DoD) to carry out conservation and natural resource rehabilitation projects on military installations in coordination with local agencies and the USFWS. Installations are required to create an Integrated Natural Resources Management Plan which describes ongoing and future conservation projects on military lands. In the Marianas, DoD manages large tracts of lands on Guam, Tinian, Pagan, and Farallon de Medinilla.

Future Scenarios

The condition of developed systems in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out, and their effects on developed systems. In the following sections we will analyze future scenarios and their possible impacts for conservation in the Marianas. The CMPs are as follows:

- (1) *Conservation values*: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and biosecurity*: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).

- (3) *Development or conservation planning*: national, territorial, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway climate change scenarios (van Vuuren et al., 2011a,b).

The four foreseeable future scenarios considered in this assessment are:

Future Scenario One, Status Quo—the most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—a slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—a slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—a moderate to high increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of developed systems in scenario one, the status quo, was characterized from an assessment of change over time in developed, developed vegetation, bare soil, and cropland land cover obtained from existing land cover maps (see Amidon and Reeves, 2018 for a description of land cover change assessment methodology). Based on these land cover maps, an annual rate of change for developed systems was estimated, and a projected change (in acres/ha) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the developed system that is expected in the foreseeable future under scenario one, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged. The future condition of developed systems for scenarios two, three, and four cannot be quantitatively estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of developed systems under scenarios two, three, and four.

Changes in human population are captured only by the changes in the developed land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation.

The island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global climate change by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions, whose full effects may take decades or centuries to manifest (Solomon et al., 2009; Jevrejeva et al., 2012). Although impacts from climate-related habitat stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future system viability.

Future Scenario One, Status Quo

Summary: Scenario one is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in the system as described below.

Description: Using the current rate of change, the acreage of developed land on the inhabited islands is expected to increase by 30% by the year 2035, reflecting generally increasing trends in human populations on these islands (Table 3; Amidon and Reeves, 2018). This expected increase in development will likely result from the conversion of native and nonnative forests to this land cover type. The anticipated changes, under scenario one, for each of the stressors affecting the developed system are given in Table 5. An expanding human population and increased development and general land use on all inhabited islands is anticipated, and therefore stressors are expected to increase at a low annual rate. Exceptions are a low to moderate annual rate of increase for development and surface air temperature, and a low annual rate of decrease for precipitation. Development of land for residential, commercial, and agricultural purposes will continue at an annual rate of 25%. This will likely lead to a decrease in developed vegetation, as developed areas increase. Because scenario one biosecurity CMPs remain unchanged while the human population and development continue to grow, an increased potential for new invasive species and new diseases (particularly those affecting native plants) exists. The introduction of additional plant diseases and invasive species, has the potential to alter the biological composition of developed vegetation, and reduce the resiliency, redundancy, and representation of this developed system type. Altered hydrology, combined with a reduction in rainfall, may enhance the conditions that support wildfires. Wildfires clear vegetation and lead to erosion, which can decrease water quality, leading to small increases the amount of pollution entering waterways.

Table 5 Responses of developed system stressors in foreseeable future scenarios.

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans.			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented.			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation).			
Foreseeable future scenarios and the resulting developed (urban and agricultural) conditions				
Use foreseeable future scenario one as a “baseline” to characterize changes in Conservation Actions and Conditions in future scenarios two, three, and four.	Scenario One: CMPs: unchanged in support for NRC/B. Conservation Actions: no change; current rate of land cover change continues through the foreseeable future. Condition: habitat area, quality, and sustainability slowly decrease through the foreseeable future.	Scenario Two: CMPs: small increase in support for NRC/B. Conservation Actions: marginal increase. Condition: habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future.	Scenario Three: CMPs: small to moderate decrease in support for NRC/B. Conservation Actions: substantial decrease. Condition: urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future.	Scenario Four: CMPs: moderate to high increase in support for NRC/B. Conservation Actions: substantial increase. Condition: robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future.
Developed system stressors	Responses of developed system stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to high increase	Small to moderate decrease
Altered Hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation/access	Small increase	Small increase	Larger increase	Larger increase
Water pollution	Small increase	No change	Larger increase	Small decrease
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Plant diseases	Small increase	Small increase	Larger increase	No change to small decrease
Fire	Small to moderate increase	Small increase	Larger increase	No change to small increase
Erosion	Small increase	No change	Larger increase	Small decrease
Climate				
Temperature	Small to moderate increase	Small to moderate increase	Small to moderate increase	Small to moderate increase
Precipitation	Small decrease	Small decrease	Small decrease	Small decrease
Sea level rise	Small increase	Small increase	Small increase	Small increase
Storms	Small increase	Small increase	Small increase	Small increase

Future Scenario Two

There is a slight increase in the CMPs that marginally improves conservation management.

Summary: Conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. There is no change in development, with areas currently occupied by development are redeveloped rather than opening new areas.

Description: Scenario two is essentially “status quo” with minor improvements in the three CMPs. The anticipated changes, under scenario two, for each of important stressors for the developed system are given in [Table 5](#). Though there is an expanding human population ([Table 3](#)) in scenario two, development is not expected to substantially increase due to redevelopment of currently developed areas (e.g., higher density housing, conversion of urban vegetated areas to impervious). A slightly improved biosecurity effort should help reduce the current rate of invasive species and plant disease invasion, but slight increases are still expected. The small increased support of natural resource management in the CMPs is not expected to greatly alter wildfire frequency and intensity, but these might lower slightly compared to scenario one. The CMPs supported conservation will not prevent, mitigate, or reverse the impacts of climate change-related stressors.

Future Scenario Three

There is a low to moderate decrease in conservation actions in the CMPs that substantially decreases conservation management.

Summary: All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible.

Description: Scenario three has substantial declines in natural resource conservation within the three CMPs. An increasing human population (**Table 3**) is supported in its use of land for economic development over the conservation of native habitats. Remnant developed vegetation and bare soil areas that cannot support development become the only areas of free-living native species within the developed system. A larger increase in invasive species and plant diseases have the potential to alter biological composition of developed system types, decreasing the resiliency, redundancy, and representation of developed systems. A larger increase in altered hydrology combined with an expected small decrease in precipitation due to climate change, are expected to lead to an increased risk of wildfires, erosion, and pollution. The anticipated changes, under scenario three, for each of the stressors relevant to the developed system are given in **Table 5**.

Future Scenario Four

There is a moderate to high increase in conservation actions in the CMPs that substantially improves conservation management.

Summary: An overt, robust, active, and ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native dominated developed systems, and to actively restore and expand these ecosystems.

Description: A substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural habitats and biodiversity. Active and well-supported natural resource management begins to restore developed systems and ecosystems and expand their landscape areas. The anticipated changes, under scenario four, for each of the stressors important for the developed systems are given in **Table 5**. The needs of an expanding human population (**Table 3**) are addressed through more efficient land use governance based on redevelopment rather than further development of undeveloped areas. Modern and novel agricultural practices focus on methods that do not affect existing natural areas, or areas needed for native wildlife restoration, and increase the productivity and resiliency on existing croplands. Substantially improved biosecurity regulations decrease introductions of invasive species and plant diseases, and prevent the spread of unestablished introduced species. These improved land management actions result in decreased wildfire frequency and extent, preventing runoff and decreasing water pollution. The substantial increase in CMPs supported conservation may locally mitigate some effects of climate change-related stressors, but climate change effects are expected to persist.

Conclusion

The primary stressor to developed systems is vegetation loss and destruction caused by development. Threats from development are significant and ongoing and are expected to continue or increase in magnitude and intensity into the future unless there are effective management actions. Current conservation efforts taken by Federal, Territorial, private, and agency partnerships combined with certain laws and regulations limit some of the effects of the stressors on the habitat, but do not eliminate them. The stressors continue to contribute to the further increase of development and loss of vegetation.

In summary, developed systems are resilient (**Table 5**), in part due to the increased capacity to recover from stochastic and natural events. However, they remain threatened by fragmentation as a result of further development, as well as the presence of nonnative vegetation. The nature of invasive plants, which are commonly found in developed and urban areas, is to create self-sustaining populations which become dominant or disruptive to native systems. The developed system is less defined by typical species across the archipelago than it is by anthropogenic influence and a dominance of nonnative species, so this land use type is considered representative due to the distribution across the islands.

The Marianas developed systems represent a unique ecosystem type, whose composition is dynamic across its range. Due to growing human population numbers, the developed system is likely to shrink in size over the coming years, as development increases. The persistence of developed systems, and reduction of overall vegetation in the archipelago means that stressors are likely to increase and biological components within the system will decrease, should substantial increases in conservation actions not be implemented. Effects from climate change are likely to occur regardless of conservation measures in place, which will increase the likelihood of compounded effects from other stressors such as erosion, wildfire, plant diseases, and invasive species. The long-term survival of biodiversity in developed systems remains under threat, so long as nonnative species dominate the landscape. The implementation of strong conservation actions are needed to address the true impacts of these stressors on the long-term viability of developed systems across the Marianas.

Abstract

The following analysis represents the results of a status assessment for the developed system in the Hawaiian Islands including its current status, stressors, conservation efforts, and future viability. The developed system occurs primarily in lowland areas with some in mid- and high elevation areas. There are five categories with varying amounts of vegetation, impermeable surfaces (e.g., roads, buildings), and permeable surfaces. Biodiversity within the developed system is lower compared to the other systems and is generally dominated by nonnative species. Currently, the developed system in Hawai'i occurs on each of the eight main Hawaiian Islands with Ni'ihau, Kaho'olawe, and the Northwestern Hawaiian Islands (NWHI) comparatively containing very little. Our assessment of developed system viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resiliency. The main stressors on the developed system are insects and disease, axis deer, fire and drought, altered hydrology, pollutants, and land use changes. Ongoing conservation efforts are helping to address each stressor. The conservation of the developed system depends on combined efforts of State, Federal, and multi-agency organizations, watershed partnerships, private landowners, and passive/social management through policies, laws, and land protection.

Developed System Description

In the Hawaiian Islands, increasing population and land use intensity has resulted in a shift in the landscape towards dense settlement and cropland anthromes (Ellis et al., 2010). Within these anthromes, developed habitat could be classified as one of five categories: open space, low-, medium-, and high-intensity development, and areas of agriculture/cultivated lands. The future scenarios viability assessment was conducted to evaluate how variations in management actions and policy decision making will likely affect the viability of these habitat types. Determination of the most likely scenario to occur in the foreseeable future will aid in determining the best course of action to maintain status quo or possibly lead to an improvement in systems functions (Gibson and Quinn, 2017).

Vegetation Structure

Developed system vegetation ranges from impermeable surfaces (e.g., roads, buildings) to permeable surfaces of regularly tilled agricultural areas, fallow agricultural and open areas, areas modified by minimal development, or areas with higher intensity use with little to no vegetation remaining (Cuddihy and Stone, 1990). Agricultural areas may be limited to one vegetation type as a commercial crop. Open areas that are fallow (untilled agricultural areas, parks, golf courses) could contain some taller vegetation providing some canopy cover (Gagne and Cuddihy, 1999). Vegetation structure of low-intensity developed habitat within untilled fields and cleared land would tend to be composed of native species that existed prior to development consisting of low-statured herbaceous plants to higher-statured woody plants (Cuddihy, 1989; Gagne and Cuddihy, 1999). Vegetation structure of a medium-intensity developed system demonstrates a range of structure from completely herbaceous to woody plants providing some canopy. Vegetation structure of a high-intensity developed system includes those with a limited range of structure depending on available space (Gagne and Cuddihy, 1999).

Vegetation Composition and Biodiversity

The vegetation composition of the developed system usually ranges from barren areas to vegetated areas, which may be very low in species diversity, with limited canopy cover, if any (GIS GAP, 2018). Studies have shown that the diversity of species declines in areas of higher intensity development (McKinney, 2002; Sax and Gaines, 2003). In addition, species composition changes in urban environments such that the number of nonnative species increases and native species decreases (McKinney, 2002). Open areas that are fallow could contain the highest levels of biodiversity; however, the flora and fauna are dominated by nonnative species (Gagne and Cuddihy, 1999). Vegetation communities of a low-intensity developed system is composed of native and nonnative species. Vegetation communities of a medium-intensity developed system include mostly nonnative species for lawns, cleared land, and small parks and gardens. Vegetation communities of a high-intensity developed system include only those left in place or planted as horticultural features as part of the development (e.g., street trees, hedges) (Gagne and Cuddihy, 1999). In summary, the vegetation composition of developed habitat is characterized by the dominance of nonnative species (Cabin et al., 2002). Fauna found in a developed system may consist of many of the same species found in more undisturbed areas (birds, insects, bats) but are limited by availability of foraging and nesting resources and by the effects of habitat fragmentation in the large spaces created between individuals and populations. For example, roads favor species with good dispersal abilities in disturbed habitats at the expense of species with limited mobility. Habitat fragmentation may pose barriers to animal movement, while increasing the connectivity of disturbed sites promoting the spread of nonnative plants, pests, and pathogens (e.g., transported by vehicles) (Noss et al., 2006).

Physical and Life History Components

Geology—Most coastal and lowland developed systems in Hawai'i overlay areas of reef, beach, and lagoon deposits, alluvium, young and old dune deposits, and basalt lava (pāhoehoe and 'a'ā) (Street, 1992; Walker, 1999; Landfire, 2016, unpublished data). Developed systems in mid- to high-elevations overlay old to young basaltic lava (GIS GAP, 2018; Landfire, 2016, unpublished data).

Water availability—The majority of the developed system occurs at lower elevations and is typically dry, with annual rainfall of < 20 in (50 cm); however, windward rainfall may be high enough (up to 40 in (100 cm)) to support mesic-associated and sometimes wet-associated vegetation (Price and Carlquist, 1999). The developed system, including impervious areas and tilled and fallow fields, overlays natural and manmade groundwater features (Mink and Bauer, 1998). Polynesian settlers used perennial streams and springs as the main sources of water and built elaborate diversions for agricultural use. Tunnel and ditch systems were constructed to transport water on every island except Kaho'olawe and Ni'ihau. More recently, drilled wells, infiltration galleries, and drainage tunnels are the most common ways used to access groundwater (Mink and Bauer, 1998).

Natural and Physical Boundaries—The developed system is bounded by the ocean and by steep cliffs or slopes that are not suitable for construction, agriculture, or other modification.

Inclusions—The developed system may also contain anchialine pools, emergent wetlands, ponds, pools, and streams with coexisting faunal species such as wetland birds, fish, anchialine pool shrimp, and damselflies (GIS GAP, 2018; Landfire, 2016, unpublished data).

Pre-Human Condition

The developed system did not occur in Hawai'i before human colonization.

Current Condition

The developed system is predominantly found on six of eight Hawaiian islands: Kaua'i, O'ahu, Moloka'i, Lāna'i, Maui, and Hawai'i. Ni'ihau is inhabited but is privately owned with no general public access to be able to obtain current data; however, satellite views

show there are no paved roads and very few small buildings and homes. Kaho'olawe has no permanent habitation, although there are a few unpaved roads and small buildings and structures for use during restoration activities. No analyses are available regarding developed habitat on the Northwestern Hawaiian Islands (Landfire, 2016, unpublished data). Pihemanu (Midway Atoll) consists of two land areas totaling 26 mi² (66 km²), one of which has unused runways and a second that is more developed with an active runway, roads and impervious surfaces, buildings to support permanent residents, and a walled harbor. Lalo (French Frigate Shoals) and Hōlanikū (Kure Atoll) both have runways in disrepair. The remaining atolls and islands: Nihoa, Mokumanamana (Necker), and 'Ōnūnui (Gardner Pinnacles) have no developed areas.

The developed system first appeared in Hawai'i when Polynesians settled the islands >1000 years ago, and their success depended upon availability of water resources, mostly for cultivation of taro and other crops (Mink and Bauer, 1998). They modified the landscape by building extensive hydraulic works to support needed agriculture. Introduced plants replaced native vegetation in succession on fallow and abandoned fields (Cuddihy and Stone, 1990). Crops (sugarcane, pineapple, and rice) were grown commercially beginning about 1835 (Ziegler, 2002). By the late 1870s, the first well was drilled on southwestern O'ahu, supplying artesian water and allowing for the great increase in numbers of residents and development. Modification of the landscape on the Hawaiian Islands continued with the onset of long-distance passenger aircraft, the end of the plantation system for sugarcane and pineapple, and a growing population with the concurrent increase in residential areas, apartment complexes, highways, and military bases (Fung Associates, Inc., 2011). In 1980, there were 18 sugar and pineapple plantations totaling >300,000 acres (ac) (121,406 hectares (ha)), but as of 2017, only 5000 ac (2023 ha) of these crops remained (Lyte, 2017, unpublished data). Currently, agriculture is dominated by small farms averaging 160 ac (65 ha) in size for production of nursery and greenhouse crops and some livestock, poultry, and their products (HDBEDT, 2017). Urban residential and commercial development in Hawai'i is more prevalent at lower elevations along the coast, although some developed areas may be at higher elevations suitable for development to occur (e.g., astronomical telescopes). Current developed system areas for each island is shown in Figs. 1–4.

Categories of the Developed System

The developed system of the Hawaiian Islands falls into five categories: (1) open space, (2) low-intensity developed, (3) medium-intensity developed, (4) high-intensity developed, and (5) agriculture/cultivation. Descriptions and examples of each category are provided in Table 1.

The five categories of developed habitat occur in different proportions on each Hawaiian island as represented in Fig. 5 (Reeves and Amidon, 2018, unpublished data). A large portion of the land area of Midway in the NWHI is developed (for access by aviation with an active runway and support facilities, and was determined by satellite imagery).

O'ahu has the largest percentage of land area within the developed system (33%), followed by Maui at 22%, Kaua'i at 18%, Hawai'i Island at 7%, Moloka'i at 6%, Lāna'i at 4%, and Ni'ihau and Kaho'olawe at 1% (as shown in Fig. 6).

Flora and Fauna Composition and Biodiversity

Species that occur in the developed system may be one of three types and can be native or nonnative. The first type, urban avoiders, consists of plant species that are sensitive to human activities and includes late successional (old growth) and wetland plants. The second type, urban adapters, consists of plant species that do well in managed lands and ruderal areas such as cultivated turfgrass, ornamental shrubs and trees, wind-dispersed lawn weeds such as dandelions and crabgrass, and bird-dispersed shrubs, trees, and weeds. Some animal species in the developed system are those that can exploit human foods and garbage, and that also benefit from fewer predators in these areas. This also includes bird species that are ground feeders, omnivores, seedeaters, and aerial sweepers. Tilled areas used for crops, and nurseries or small parks and gardens may be considered as urban adapters, but can only persist when being actively managed. The third type, urban exploiters, depends on human resources and not on the amount or types of vegetation. These are mostly animal species including house sparrows, Norway rats, mice, cats, mongoose, and insects such as cockroaches. Plants that are urban exploiters include those species that can tolerate disturbance (mostly grasses and annuals) and that have wind-dispersed seeds, a tolerance of pollution, trampling, and alkaline compacted soils (McKinney, 2002). Species are sustained through their redundancy, resiliency, and representation. These terms can also describe the viability of different systems, including the developed system. System viability depends on maintenance of multiple and distributed populations (redundancy) of sufficient quality and size (resiliency) with biological richness and genetic range (representation) to persist over time.

Landownership

One of the NWHI, Midway Atoll (an Unincorporated Territory administered by the U.S. Fish & Wildlife Service as a National Wildlife Refuge), consists of three islets, one of which (Sand Island) is almost entirely developed habitat (actively used runways and buildings). Of the remaining Hawaiian islands, O'ahu has the greatest land area of developed habitat, 32%, consisting of 122,313 ac (49,498 ha) with the largest portion (over 82,000 ac; 33,184 ha) privately owned. Maui is the second most developed island (over 21%), consisting of 99,478 ac (40,257 ha) of developed habitat with the largest portion (over 89,000 ac; 36,017 ha) privately owned. Kaua'i consists of almost 18% developed habitat (almost 64,000 ac; 25,900 ha) with the largest portion (almost 39,600 ac; 16,026 ha) privately owned. The island of Hawai'i consists of nearly 7% developed habitat (almost 173,000 ac; 70,010 ha) with the largest portion (almost 138,000 ac; 55,845 ha) privately owned. Moloka'i consists of about 6% developed

habitat (10,420 ac; 4217 ha) with a little over 6000 ac (2428 ha) privately owned. Lāna'i consists of almost 4% developed habitat (almost 3400 ac; 1376 ha) with nearly all being privately owned, Ni'ihau consists of <1% developed habitat all of which is privately owned. Kaho'olawe consists of <1% developed habitat all of which is state-owned ([Hawaii State Office of Planning, 2017](#)). This information is summarized in [Table 2](#).

Stressors

Insects and disease, axis deer, fire and drought, altered hydrology, pollutants, and land use changes are stressors that affect the developed system. Below are descriptions of the most significant stressors and their impacts on the developed system.

Table 1 Developed system categories.

Category	Description	Examples
Open space	Mostly vegetated, primarily lawn grass, some construction materials, < 20% impervious surfaces	Large-lot single-family housing units, parks, golf courses, and vegetation planted for erosion control, aesthetic purposes, or recreation areas
Low-intensity	Mixture of constructed materials and vegetation and 20–49% impervious surfaces	Single-family housing units
Medium-intensity	Mixture of constructed materials and vegetation and 50–79% impervious surfaces	Single-family housing units
High-intensity	Highly developed areas where people reside or work in high numbers and 80–100% impervious surfaces	Apartment complexes, row houses, and commercial/industrial use
Agriculture	Planted lands of variable physiognomy	May include ordered rows of plantings in agricultural-zoned lowland mesic and wet settings with a wide variety of dominants of taller-statured plants (e.g., banana and papaya), and shorter-statured crops (e.g., vegetable crops) and fallow fields

From: Landfire. (2016), unpublished data, Landfire/GAP land cover map unit descriptions, based on NatureServe Ecological Systems. 1398 pp.

Insects and diseases—Pest species such as nonnative insects and diseases can be introduced to Hawai'i through import of cargo and plants through ports and then move from one island to another by inter-island transport. Existing State and Federal regulatory mechanisms do not adequately prevent the introduction of these pests and diseases (HDLNR DAR, 2003). Below we provide examples of two insect pests recently introduced to Hawai'i that affect the developed system and the consequences of their introduction.

The coconut rhinoceros beetle (CRB) (*Oryctes rhinoceros*) is native to tropical and subtropical southeastern Asia and is one of the most damaging insects to coconut and African oil palm trees (Bedford, 2015, unpublished data). Adult beetles bore their way into the crown of healthy palms or plants and then bore outward through the base of a central palm frond (Molet, 2013). It is unknown

when it was introduced to Hawai'i, but it was first detected on O'ahu in December 2013 at Pearl Harbor-Hickam Joint Base (USDA-APHIS, 2015, unpublished data). This insect quickly spread across the southwest portion of O'ahu within a few months after detection (USDA-HDOA, 2014, unpublished data). The CRB has the potential to devastate populations of native and nonnative palms and agricultural crops in Hawai'i including pandanus, banana, and pineapple by damaging and killing individual trees, reducing crop yields, and by increasing costs to implement control measures and replacing plants (HISC, 2018a, unpublished data).

Table 2 Developed system landownership (acres, hectares).

<i>Island</i>	<i>Federal</i>	<i>State</i>	<i>County</i>	<i>Private</i>	<i>Other</i>	<i>Total developed</i>	<i>Percent developed</i>

Ni'ihau	0	0	0	333	0	333	0.7
	0	0	0	135	0	135	

The *Erythrina* gall wasp (*Quadrastichus erythrinae*) is native to Africa and was first discovered on O'ahu in April 2005 in native wiliwili trees (*Erythrina sanduicensis*) in native forest and in nonnative *Erythrina* trees or coral trees (*E. variegata*) used for landscaping and windbreaks around farmsteads (Rotar et al., 1986). The gall wasp has caused substantial impacts to the native wiliwili trees and to the agricultural industry in Hawai'i (Rubinoff et al., 2010). It quickly spread and by October 2005, it was reported on all of the main Hawaiian islands except Ni'ihau (Heu et al., 2008, unpublished data). Wasps lay their eggs in young leaves and stems and as the larvae develop, galls form in the leaflets and petioles (Heu et al., 2008, unpublished data). Leaves and stems with many galls reduce plant growth and vigor, defoliate trees and cause death of trees (Yang et al., 2004). The gall wasp has almost eliminated Moloka'i's coral tree population; therefore, farmsteads that used coral trees as windbreaks must now manage wind damage to their crops in other ways (Tizon, 2007, unpublished data).

In addition to the insect introductions described above, plant diseases already introduced to Hawai'i such as banana bunchy top, papaya mosaic virus, and powdery mildew (all transmitted by insects) affect agricultural areas of the developed system and move from those areas to other previously unaffected areas, possibly affecting other native and nonnative plant and invertebrate species. These stressors decrease the resiliency of the developed system, leading to less redundancy necessary for continued representation.

Feral ungulates—Axis deer (*Axis axis*) were introduced to Moloka'i (eight animals in 1868, increasing to over 1000 in 20 years), Lāna'i (1920), and Maui (1960), and illegally released on the island of Hawai'i in 2010 (Tomich, 1986; BigIsland.com, 2011, unpublished data). Axis deer browse on a wide variety of trees and shrubs in native forest, fruits and vegetables on agriculture lands as well as plantings in more intensely developed areas. Axis deer have high reproductive rates, and in the absence of predators have population growth rates as high as 20–30% (Hess, 2008). The estimated cost of axis deer damages to farms, ranches, and resorts in Maui County for a two-year period was calculated at over 2 million dollars (The Economic Research Organization at the University of Hawaii (UHERO), 2016). Other feral ungulates such as pigs (*Sus scrofa*), goats (*Capra hircus*), cattle (*Bos taurus*), and mouflon (*Ovis musimon*) may affect the developed system by trampling leading to erosion, and by herbivory of plant species; however, we have no direct evidence of this occurring on a large scale within the developed system.

Fire and drought—In Hawai'i, over 1000 wildfires burn >17,000 acres annually and the amount of area burned each year is increasing (Pacific Fire Exchange, 2014, unpublished data). The majority of wildfires are human caused (arson, fireworks, trash, cooking accidents, vehicle-caused wildfires, agricultural fires) that get out of control (HDLNR-DOFAW, 2016) with the highest density (66%) of ignitions occurring within developed areas (Trauernicht et al., 2015) (Fig. 7).

Wildfires affect the developed system by increasing the amount of fire-prone invasive grasses (e.g., guinea grass (*Megathyrsus maximus*), buffelgrass (*Pennisetum ciliare*), fountain grass (*Cenchrus setaceus*), and molasses grass (*Melinis minutiflora*)), which in turn increases the risk for wildfires, creating a grass-fire cycle. These fire-prone species quickly invade burned areas, creating areas dominated by fine continuous fuel loads that are easily ignitable and carry fire quickly across the landscape (Smith and Tunison, 1992; HDLNR-DOFAW, 2016). Wildfires destroy vegetation and heavy rainfalls following wildfire events increase soil erosion and landslides, leading to increased sedimentation of streams, wetlands, and downstream systems (e.g., coral reefs) (Pacific Fire Exchange, 2014, unpublished data; HDLNR-DOFAW, 2016). Increased sedimentation causes continued degradation of streams, stream flow, and wetlands, and prevents these systems from properly functioning.

Altered hydrology and soil composition—Hawai'i has experienced drought conditions throughout history, with increasing and longer episodes in the past 15 years (Hawaii Civil Defense, 2011). Site clearing, grading, and converting pervious surfaces (e.g., vegetated areas) to impervious surfaces (actions associated with the developed system) alters hydrology by increasing runoff, erosion, and sediment into surface waters (HDBEDT, 1994). The conversion of pervious surfaces to impervious (e.g., rooftops, roads, parking lots, sidewalks) decreases the ability of the ground to filter runoff thereby increasing runoff (HDBEDT, 1994). To address

Fig. 7 Recorded wildfire incidents in the main Hawaiian Islands from 1900 to 2013. Map produced by the United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office.

elevated flows from increased runoff and to prevent streambank erosion, runoff conveyances are constructed or drainages are modified (HDBEDT, 1994). Other examples of changes to hydrology due to urbanization include higher peak discharges, increased volume of urban runoff during storms, increased frequency and severity of flooding, and reduced streamflow during drought conditions (HDBEDT, 1994). Increased runoff also results in less water being available for consumptive use; therefore less water is available for agricultural uses.

The dominant water source in Hawai'i is groundwater, either as a basal lens floating on seawater, or as high-level water. Perennial streams and springs are important water supplies for large-scale agriculture and most large streams are diverted for irrigation (using tunnel and ditch systems). Some tunnels act as drains for use of high-level groundwater. As of the mid-1990s, groundwater extraction for human and agricultural use remained below sustainable yields (Mink and Bauer, 1998). Potential over-pumping of groundwater is controlled through the Commission on Water Resources Management's defined sustainable yield determinations, and production would be reduced or shifted to other aquifers that are not over the defined yield (Hawai'i Board of Water Supply, 2016). However, the basal water level is currently less than half of its volume of 100 years ago (Mink and Bauer, 1998).

Intensive farming practices in Hawai'i that rely on tillage and synthetic fertilizers tend to decrease the soil's mineralizable N (available nitrogen) pool. Nitrogen mineralization decreases primarily because conventional farming practices decrease organic matter. For both the Hawaiian Waimea (very fine sandy loam) and Waialua (silty clay) series soils, long-term cultivation decreased nitrogen mineralization by a factor of 30. This also indicates low microbial activity and degradation of the biological properties of the soil. Sustained over-use of farmlands without best management practices would continue to degrade soil nutrients and possibly compact the soil making it less water-permeable. Mitigation for this loss would take sustained application of large amounts of organic matter over several years (Deenik, 2006).

Pollutants—Urban and agricultural areas are a source of pollutants (e.g., sediment nutrients, bacteria, toxic chemicals, oil, and trash) that enter into streams, wetlands, coastal areas, and the ocean (HDBEDT, 1994). Roads, buildings, parking lots, and other non-permeable surfaces prevent rainwater from soaking into the ground and increases the volume and speed of water runoff, increasing soil erosion, and flushing pollutants into streams and through storm drains to the ocean.

Land use zoning changes—There are four land use districts in the State of Hawai'i: Agriculture, Conservation, Rural, and Urban. Statewide, the majority of land falls within Conservation or Agriculture districts (both of which do not allow major development), with O'ahu being the exception since a fair amount falls within the Urban district (101,661 ac, 41,141 ha) (HDBEDT, 2017). As areas are reclassified from agriculture to urban, major development within the urban land use district can change the ecological function of the existing system. Undeveloped areas, that were or could be used for agriculture or left as open space, when reclassified

for urban use and developed, exhibit increases in water runoff and sedimentation by surface changes from permeable to non-permeable.

Conservation Efforts for the Developed System

There is active (on-the-ground) management of invasive species, wildfire, and water resources in the developed system through cooperative efforts of State agencies, Federal agencies, watershed partnerships, private organizations, and individual landowners and passive/social management of the developed system through policies, laws, and other land protections.

Invasive Species

The effects of invasive species on the developed system are addressed in several ways. The Hawai'i Invasive Species Council (HISC) established in 2003 was created to implement invasive species management statewide ([HISC, 2018b, unpublished data](#)). Invasive species committees (ISCs) are voluntary partnerships of government, private, and non-profit organizations. Five Hawaiian islands have separate smaller committees to address island-specific issues: Hawai'i (BIISC), Maui (MISC), Moloka'i (MoMISC), O'ahu (OISC), and Kaua'i (KISC). These committees identify and prioritize invasive species (plants and animals) for control or eradication, including recent developed habitat invaders such as the *Erythrina* gall wasp and the coconut rhinoceros beetle discussed in "Insects and Diseases."

Hawai'i's Department of Transportation (HDOT) established the Highway Division's Statewide Noxious and Invasive Pest Program (SNIPP) that has prepared a 10-year strategic plan to steward lands affected by the highway system ([HDOT, 2011](#)). This plan is implemented in cooperation with stakeholders in the public and private sectors. The plan determines funding needs for prevention of invasive species establishment, early detection and response, control and management, restoration, and community and organizational outreach. Funding costs to implement the plan are included as part of construction project work plans and federal funds are available at an 80:20 match for the annual SNIPP budget. The stakeholders include the ISCs, the Department of Land and Natural Resources (DLNR), the Hawai'i Department of Agriculture (DOA), the U.S. Department of Agriculture (USDA), the University of Hawai'i-College of Tropical Agriculture and Human Resources (UH-CTAHR), the U.S. Fish and Wildlife Service (USFWS), The Sierra Club, and The Outdoor Circle. The HDOT also provides guidelines for landscape maintenance and pruning of trees, shrubs, palms, and hedges along roadways ([State of Hawai'i, 2011](#)). The actions require obtaining a contractor's license, insurance, and use of an International Society of Arboriculture Certified Arborist. The HDOT describes pruning techniques, risk assessment, and guidelines for native planting. The Certified Arborist must work in coordination with an HDOT engineer and be aware of all federal, state, and county regulations.

The invasive nonnative ungulate most likely to affect the developed system is the axis deer ([Martin, 2011, unpublished data](#)). Axis deer are provided and maintained by the State as a hunting resource on Maui, Lāna'i, and Moloka'i. The State does not permit their introduction to other Hawaiian islands. In response to axis deer being illegally released on the island of Hawai'i in 2010, the DLNR has developed a response and removal plan, including a partnership with the DOA, the BIISC, Federal agencies, and private landowners ([BigIsland.com, 2011, unpublished data](#)). In addition, the BIISC prepared House Bill 2593 to amend the Hawai'i Revised Statute 91, which allows agencies to adopt emergency rules in instances of imminent peril to public health, including livestock and poultry health ([Martin, 2011, unpublished data](#); [Aila, 2012, unpublished data](#)). The rule was enacted into law in 2012 and allowed for a rapid response and removal of axis deer from the island of Hawai'i ([State of Hawai'i, 2012, unpublished data](#)).

The Hawai'i DOA established a "Noxious Weed List" of plants that are not allowed to be imported into the state; however, this list is not comprehensive and does not prevent importation of all potentially invasive plants (HAR 1981-Title 4, Subtitle 6, Chapter 68). The Department of Homeland Security-Customs and Border Protection (DHS-CBP) is responsible for inspecting commercial, private, and military vessels and aircraft, and related cargo and passengers arriving from foreign locations ([DHS-CBP, 2017, unpublished data](#)). However, CBP focuses on quarantine issues involving non-propagative plant materials; wooden packing materials, timber, and products; internationally regulated commercial species under CITES; and federally listed noxious plants, seeds, soils, and pests of concern to the continental United States, such as pests to mainland U.S. forests and agriculture. In 2011, House Bill 865 amended the statute to increase the fee imposed for inspection, quarantine, and eradication of invasive species contained in freight brought into the State (from 50 cents to 75 cents per 1000 pounds of freight) in an attempt to provide enough funding for enforcement of existing regulations ([HDOA, 2011, unpublished data](#)).

The Agricultural Research Service (ARS) is the chief scientific research agency for the USDA, and conducts research to find solutions for agricultural problems, including biocontrol. Because of the severity of the effects of the *Erythrina* gall wasp on native plants, agriculture and the plant industry, the ARS conducted a search for an effective biocontrol. A wasp from East Africa, *Eurytoma erythrinae*, a known predator of the *Erythrina* gall wasp, was extensively tested and ultimately released to help bring the *Erythrina* gall wasp infestation under control ([HDOA-ARS, 2010, unpublished data](#)). A later study showed that the success of the predatory wasp was dependent on local environmental factors such as drought which contributed to poorer health of the infected plants overall. A higher success of the predatory wasp is expected over the long term as populations of the *Erythrina* gall wasp decline ([Bell et al., 2013](#)).

Fire

Wildfires are most frequent in developed areas (but these are not the largest areas in acres consumed) (see Fig. 7). The Hawai'i Division of Forestry and Wildlife (DOFAW) and Hawai'i Wildfire Management Organization (HWMO) have adapted national fire education resources to local contexts in Hawai'i (Trauernicht et al., 2015). Fuel breaks are expensive to maintain in Hawai'i because of the terrain and year-round plant growth. Hawai'i's fire management community has had to consider alternate fuels management strategies to reduce fuels. The four county fire departments of Hawai'i, Kaua'i, Maui, and O'ahu respond to building, vehicle, wild-land, trash, and marine vessel fires, but are primarily trained and equipped for structural fires. The Hawai'i Division of Forestry and Wildlife (DOFAW) is the primary responder for wildfires on State land; however, DOFAW does not employ full-time firefighters. These agencies have mutual aid agreements, and can assist each other or be assisted by Federal agencies at Hawai'i Volcanoes National Park and the U.S. Army Garrison on Oahu or Hawai'i. Because fires are most frequent in the developed system, reducing these fires require addressing issues such as human behavior, public safety, education, economics, and disaster response.

Watershed and Water Resources Management

With the demise of plantation agriculture in Hawai'i in the 1990s (sugarcane and pineapple), large amounts of agricultural land and irrigation systems were made available. In response, the State plans to strengthen and expand the diversified agriculture industry. The agricultural water use and development plan prepared by the HDOA analyzes the needed capital improvements along with providing estimates of future water usage and agricultural needs (HDOA, 2003).

There are 16 Soil and Water Conservation Districts (SWCDs) in Hawaii, with a board that operates on a voluntary basis in partnership with the USDA-Natural Resources Conservation Service (NRCS). The NRCS enters into agreements (through the Farm Bill) with landowners to maintain their land-use operations according to NRCS standards by managing conservation plans that result in soil savings, reduction of sedimentation, control of invasive species, and reforestation of riparian buffers and declining habitats (HDLNR-DWLM and USDA-NRCS, 2012, unpublished data). Because soil acts as a water "filter" by buffering, degrading, and immobilizing various pollutants (e.g., chemicals, pesticides, nutrients), emphasis is placed on employing practices of conservation and sustainable use of the land (HDLNR-DWLM and USDA-NRCS, 2012, unpublished data).

The State's Commission on Water Resource Management (CWRM) also recognized the need to update the 2008 water resource protection plan; however, interim flow standards remain at status quo (no increase or decrease in the current stream flow rates) (CWRM, 2014, unpublished data). Recently, in-stream flow standards were set for four West Maui streams: Ukumehame Stream, Olowalu Stream, Kaua'ula Stream, and Launiupoko Stream (The Maui News, 2018, unpublished data). The CWRM Initiative report describes management measures, practices, and goals for watershed management in low- to high-intensity developed systems and golf courses, including those for storm water control, erosion prevention, sedimentation, movement of toxic substances. The report details each local agency's responsibilities for implementation of management measures and determines which regulatory and non-regulatory mechanisms are in place (HCZM, 2015).

Watershed partnerships are voluntary alliances of public and private landowners committed to protecting over 2 million acres of watershed lands in Hawai'i (Hawaii Association of Watershed Partnerships (HAWP), 2018, unpublished data). Partnerships are established on five islands: Hawai'i, Maui, Moloka'i, O'ahu, and Kaua'i. Most of the protected areas are in non-developed habitat; however, about 20,000 ac (8000 ha) of the developed system fall within areas of watershed partnership jurisdiction, depending on the water resources. The partners provide funding and other support, such as allowing construction of ungulate enclosure fencing on their properties. They also implement invasive plant removal, create fire buffer areas, and conduct predator control.

Vegetation Management

Landscape maintenance and tree pruning in developed habitat is also regulated by State, county, and federal laws. The City and County of Honolulu has rules and regulations regarding planting and maintenance of street trees with enforcement of penalties for violation of any provision of the rules (City and County of Honolulu, 1971). For example, street trees have other protections, e.g., protections for a seabird, the white tern or manu o kū (*Gygis alba*). The white tern occurs in the Pacific islands, but in Hawai'i is found only on O'ahu in low- to high-intensity developed systems of Honolulu (Pacific Rim Conservation, 2017, unpublished data). The O'ahu population is considered Threatened by the State of Hawai'i, but currently has no federal status. Besides the threat of predation by cats, rats, and barn owls, and egg and chick mortality from strong winds; careless tree trimming can also result in loss of eggs and chicks. Private, county, State, and federal organizations provide information to arborists and the general public regarding tree trimming if the birds are present. State and federal law prohibits disturbance of white terns and their eggs and chicks. Agencies do not allow trimming of trees while white terns are occupying them for nesting, and penalties for disturbance (fines) are in place.

The USDA-NRCS, the National Center for Appropriate Technology (NCAT), and the Hawaii College of Tropical Agriculture and Human Resources (CTAHR) provide recommendations to farmers regarding best farming practices including soil testing (for fertility and quality), erosion prevention, conservation tillage to improve water conservation, planting and harvesting flexibility, and improving soil tilth (condition) (CTAHR, 2018, unpublished data; NCAT, 2015, unpublished data; USDA-NRCS, 2018, unpublished data).

Open Space

There are rules and regulations concerning an “open space requirement” for low-, medium-, and high intensity developed systems. Open space is defined as noncontiguous, unbuilt, and unobstructed spaces at-grade between and adjacent to public and private structures, and must be maintained as a recreational or social facility. For example, the Kaka’ako Community Development District enforced incorporation of 54 ac (22 ha) of public recreation space and 16 ac (6.5 ha) of private recreation space (decks on private property) for any building construction in the Kaka’ako (downtown Honolulu) area ([HCDA, 2013, unpublished data](#)).

Stakeholder Engagement

The HWMO has an on-the-ground wildfire education program and facilitates Community Wildfire Protection Plans across the State. In addition, HWMO collaborates with fire responders, land managers, and the general public to foster environmental and cultural stewardship and implement projects that address land development and planning ([HWMO, 2018, unpublished data](#)).

The Conservation Fund provides partnership opportunities for residents and organizations to protect natural resources while also focusing on community development. >4000 ac (1619 ha) have been preserved on Maui for public use in partnership with the National Park Service. A strategic conservation plan for Kona on the island of Hawai'i includes a framework for guiding future land development and conservation decisions for North and South Kona. This plan includes recommendations to enhance green infrastructure and urban water management with selected areas for growth and for rural watershed lands ([The Conservation Fund, 2018, unpublished data](#)).

The Outdoor Circle is a non-profit organization founded in 1912, with the primary mission of protecting and enhancing the environment of Hawai'i for future generations. Members first established urban green spaces by planting trees, establishing public parks and gardens, and were instrumental in banning placement of advertising billboards. They continue work with each county specific to the needs of the local communities, plant and protect trees and open space, provide environmental education, and promote community beautification ([The Outdoor Circle, 2018, unpublished data](#)).

The USDA-NRCS, in cooperation with State and county agencies, published a booklet for public distribution describing the various ways the public can contribute to resource conservation in the developed system ([USDA-NRCS, 2012, unpublished data](#)). The booklet describes many conservation practices including composting, managing beneficial and harmful insects, managing native and invasive plants (including xeriscaping and soil management), and water conservation and storm water control methods, with references and links to other information resources.

Interactions of Stressors and Conservation Efforts

The developed system in Hawai'i is primarily under private ownership (358,652 ac, 145,141 ha), more than five times as much as under State ownership (69,200 ac, 28,004 ha), therefore, any benefits of conservation actions are primarily accomplished through voluntary measures ([Hawaii State Office of Planning, 2017](#)). Areas of developed systems under State ownership benefit from State conservation and protection rules and regulations as enforced by State agencies or private organizations in partnership with the State.

Invasive species already in Hawai'i require intensive long-term management actions (coconut rhinoceros beetle, *Erythrina* gall wasp). The Invasive Species Committees (ISCs) on each island have a better chance of effective control of invasive plants and animals by using methods for rapid response (detection) and control (eradication). Some recent examples of invasive plant species quickly intercepted and controlled by the ISCs are *Nasella tenuissima* (Mexican feather grass), *Cryptostegia grandiflora* (rubber vine), and *Melinis nerviglumis* (ruby grass) ([HISC, 2018c, unpublished data](#)).

Fire is one of the major threats to the developed system. Implementation of fire management plans by private and State landowners contributes the most to fire prevention, along with efforts to foster educational programs concerning fire and environmental stewardship for private landowners and land managers.

Watershed and water resources management actions are implemented in the developed system by enforcement of state and county laws and regulations. Watershed partnerships play a large part in conservation at the landscape level, and involve cooperation between private, state, county, and agencies.

Vegetation management is conducted at a smaller scale, through both private and State actions, with some contributions at the federal level (USDA-NRCS) regarding best management practices for agriculture.

Provision of open space is part of residential construction requirements (implemented mostly through private landowners).

Stakeholder engagement and cooperation between landowners and State and federal agencies provides benefits of educational programs, conservation planning for community development, and planning for urban green spaces and green infrastructure.

The conservation efforts currently conducted and discussed above limit some of the effects of the stressors on the developed system, but do not eliminate them. The stressors continue to contribute to the further increase in area of the developed system and the increase in loss of species diversity, loss of water resources, and degradation of agricultural land and open areas.

Future Scenarios

The condition of the developed system in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

1. *Conservation values*: Stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
2. *Laws and biosecurity*: National, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented (e.g., hunting regulations, Clean Water Act, Endangered Species Act; and local laws, etc.).
3. *Development or conservation planning*: National, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011a, 2011b; Miller, 2018, unpublished data).

The four foreseeable future scenarios considered in this assessment are:

Future Scenario One, Status Quo—The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—A slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—A moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of the developed system in Scenario One, the status quo, was characterized from an assessment of change over time in developed land cover obtained from existing land cover maps (Amidon and Reeves, 2018, unpublished data). Based on these land cover maps, an annual rate of change for the developed system was estimated, and a projected change (in acres/hectares) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the developed system that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged (Table 3).

The future conditions of the developed system for Scenarios Two, Three, and Four cannot be quantitatively (acres/hectares) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of the developed system under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the developed land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018, unpublished data). Impacts from other sources of human activities or human-caused system stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation. An assessment of island-by-island changes in human population is described by Miller (2018, unpublished data).

Also note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions that occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related system stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future system viability.

Table 3 Summary of overall condition for the developed system categories in the future scenarios.

<i>Developed habitat category</i>	<i>Scenario 1: Status quo</i>	<i>Scenario 2: Slightly improved</i>	<i>Scenario 3: Substantially decreased</i>	<i>Scenario 4: Substantially improved</i>
Open space	Slight increase	Slight increase	Decrease	Increase
Agriculture and cultivated land	Decrease	Slight increase	Decrease	Slight increase
Low, medium, and high-intensity developed	Increase	Slight increase	Significant increase	Slight to moderate decrease or redevelopment

Future Scenario One, Status Quo

Summary: Scenario One is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in the system, as described below.

Description: Using the current rate of change, the land cover for the developed system was calculated for the year 2035 (Amidon and Reeves, 2018, unpublished data). The projected change in land cover by 2035 is the only future scenario with quantitative values (acres or hectares). An expanding human population and increased development and general land use on all inhabited islands is anticipated, and therefore system stressors are expected to increase at a low annual rate. Scenario One has the greatest likelihood of occurring in the foreseeable future. The anticipated changes, under Scenario One, for each of the stressors affecting each category of the developed system are described below and are given in Table 4.

Developed system-open space: The current amount of open space on each island will see increases at the status quo rate, with proportionally little gain or loss of area (approximately $\pm 2 \text{ mi}^2$, $\pm 5 \text{ km}^2$) (Amidon and Reeves, 2018, unpublished data). Conservation values will stay the same. Government agencies, non-profit organizations, and private landowners will continue to contribute resources to conserve open space. Laws and regulations will be enforced with no changes or only a slight increase in effectiveness. Pollution, invasive plants and animals (axis deer, insects), and the numbers of wildfires, will increase at status-quo rates, and there will be a slight increase in altered hydrology and recreation/human access (land use). Climate change-associated stressors such as drought (and higher temperatures) will be slight to moderate and localized (Table 4). Climate change models are predicting a decrease in rainfall for the remainder of this century (HDLNR-DOFAW, 2016). The decrease in rainfall will worsen drought conditions in the developed system, impacting farmers, cattle ranchers, and individuals who rely on catchment water systems (Hawaii Civil Defense, 2011). Drought also increases thereby increasing the potential for wildfires (Hawaii Civil Defense, 2011). Resiliency of open space will remain at status quo levels, with a slight decrease for the foreseeable future, due to pressure from continued growth of impervious areas and the associated increase of low- to high-intensity development and continued low-level impacts

Table 4 Responses of the developed system stressors in foreseeable future scenarios.

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable future scenarios and the resulting developed system conditions				
	Scenario One:	Scenario Two:	Scenario Three:	Scenario Four:
Use Foreseeable Future Scenario One as a “baseline” to characterize changes in <i>Conservation Actions</i> and <i>System Conditions</i> in Future Scenarios Two, Three and Four	<i>CMPs:</i> Unchanged in support for NRC/B <i>Conservation actions:</i> No change; current rate of land cover change continues through the foreseeable future <i>System condition:</i> System area, quality, and sustainability slowly decrease through the foreseeable future	<i>CMPs:</i> Small increase in support for NRC/B <i>Conservation actions:</i> Marginal increase. <i>System condition:</i> System area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future	<i>CMPs:</i> Small to moderate decrease in support for NRC/B <i>Conservation actions:</i> Substantial decrease <i>System condition:</i> Urban and agricultural uses are prioritized over conservation; system area, quality, and sustainability substantially decrease through the foreseeable future	<i>CMPs:</i> Moderate to high increase in support for NRC/B <i>Conservation actions:</i> Substantial increase <i>System condition:</i> Robust, sustained effort to restore, manage, and expand conservation; system area, quality, and sustainability substantially increase through the foreseeable future
System stressors				
Development	Small to moderate increase	No change (redevelop)	Moderate to large increase	Small to moderate decrease
Altered hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation access	Small increase	Small increase	Larger increase	Larger increase
Water pollution	Small increase	No change	Larger increase	Small decrease
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Plant diseases	Small increase	Small increase	Larger increase	No change to small decrease
Fire	Small to moderate increase	Small increase	Larger increase	No change to small increase
Climate				
Temperature	Small to moderate increase	Small to moderate increase	Small to moderate increase	Small to moderate increase
Precipitation	Small decrease	Small decrease	Small decrease	Small decrease
Sea level	Small increase	Small increase	Small increase	Small increase

of stressors. Those islands currently with a smaller amount of open space (Moloka'i, O'ahu), relative to the islands of Lāna'i and Ni'ihau, may see more significant effects from stressors because the amount of open space is smaller initially, resulting in less redundancy and representation of this habitat (see Figs. 1–4). Although an analysis was not done specifically for Midway Atoll, we expect the amount of open space to remain the same at status quo levels, keeping in mind the possible rise in sea level (and concurrent loss of open space) at a future time period beyond 2035.

Developed system—Agriculture/Cultivated land: Agricultural/cultivated areas will lose the largest amount of area (almost 10 mi², 26 km²) of all the categories of the developed system (Amidon and Reeves, 2018, unpublished data). Moloka'i will lose 6%, O'ahu will lose 32%, Hawai'i will lose 49%, and Kaua'i will lose 100% (Table 5). There is no calculated change in area for Kaho'olawe, Lāna'i, or Ni'ihau. This loss may contribute to the continued increase in one or more of the other developed system categories: open space, and impervious areas of low- to high-intensity developed system. Conservation values will stay the same. Government agencies, non-profit organizations, and private landowners will continue to contribute resources to conserve agricultural areas. Laws and regulations will be enforced with no changes or only a slight increase in effectiveness. Pollution, invasive plants and animals (axis deer, insects), and the numbers of wildfires, will increase at status-quo rates, and there will be a slight increase in altered hydrology and recreation/human access (open space use). Climate change-associated stressors such as drought (and higher temperatures) will be slight to moderate and localized (Table 4). Resiliency of agriculture/cultivated land will remain at status quo levels, with a slight decrease for the foreseeable future, due to pressure from continued growth of impervious areas associated with low- to high-intensity development and continued low-level impacts of stressors. Those islands currently with a smaller amount of agricultural/cultivated land (Lāna'i, Kaho'olawe), relative to the islands of Kaua'i, Maui, and Hawai'i, may see more significant effects from stressors because the amount of agricultural/cultivated land is smaller to begin with, resulting in less redundancy and representation of this habitat (see Figs. 1–4).

Developed system—Low-intensity developed, medium-intensity developed, and high-intensity developed: Impervious surfaces associated with the three levels of intensely developed habitat will increase slightly at the status quo rate, with proportionally small gains in area (approximately 4 mi², 10 km²) (Amidon and Reeves, 2018, unpublished data). Kaua'i will gain 16% of developed habitat, Hawai'i will gain 14%, Maui will gain 12%, O'ahu will gain 6%, Lāna'i will gain 4%, and Moloka'i will gain 1% (Table 5). There is no calculated change in the amount of developed area for Kaho'olawe and Ni'ihau. Conservation values will stay the same. Government agencies, non-profit organizations, and private landowners will continue to enforce provisions of open space and recreational use areas concurrent with development. Laws and regulations will be enforced with no changes or only a slight increase in effectiveness. Pollution, invasive plants and animals (axis deer, insects), and the numbers of wildfires, will increase at status-quo rates, and there will be a slight increases in altered hydrology and recreation/human access (land use). Climate change-associated stressors such as drought (and higher temperatures) will be slight to moderate and localized (Table 4). Resiliency of low- to high-intensity developed habitat will remain at status quo levels, with an increase for the foreseeable future, due to continued growth of impervious areas associated with this habitat and continued low-level impacts of stressors. Those islands currently with the smallest amounts of low- to high-intensity developed habitat (Ni'ihau, Kaho'olawe) may not see significant increases of this habitat type because of their generally slower growth rate. The islands with a moderate amount of low- to high-intensity developed habitat (Lāna'i, Moloka'i, Hawai'i) may see a more significant increase in the amount of these categories, resulting in more redundancy and representation of this habitat (see Figs. 1–4). Although an analysis was not done specifically for Midway Atoll, we expect the amount of low- to high-intensity developed space to remain the same at status quo levels, keeping in mind the possible rise in sea level (and concurrent loss of low- to high-intensity developed habitat) at a future time period beyond 2035.

Table 5 Estimated acreages and percent of island in developed systems currently (2012) and in the foreseeable future (2035) for the Hawaiian Islands (excluding the Northwestern Hawaiian Islands) (Amidon and Reeves, 2018).

System	Island	Current (2012)		Future (2035)		
		Acres	% of Land	Acres	% of Land	% Change 2012–35
Developed	Hawai'i	76,064	3	87,090	3	14
	Maui	34,550	8	38,528	8	12
	Kaho'olawe	149	1	149	1	0
	Lāna'i	3227	4	3369	4	4
	Moloka'i	6658	4	6743	4	1
	O'ahu	90,052	24	95,053	26	6
	Kaua'i	28,402	8	32,949	9	16
	Ni'ihau	332	1	332	1	0
Cultivated	Hawai'i	96,858	4	96,403	4	0
	Maui	64,928	14	33,328	7	–49
	Kaho'olawe	0	0	0	0	0
	Lāna'i	112	0	112	0	0
	Moloka'i	3760	2	3533	2	–6
	O'ahu	32,261	9	22,031	6	–32
	Kaua'i	35,324	10	0	0	–100
	Ni'ihau	0	0	0	0	0

Future Scenario Two

There is a slight increase in the CMPs that marginally improves conservation management. Scenario 2 has the third most likelihood of occurring in the foreseeable future.

Summary: Conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of the developed system.

Description: Scenario Two is essentially “status quo” with minor improvements in the three CMPs. Though there is an expanding human population in Scenario Two, development is not expected to substantially increase. Slightly improved biosecurity efforts should help reduce invasive species and plant diseases but increases are still expected. The small increased support of natural resource management in the CMPs is not expected to greatly alter wildfire frequency and intensity, but these might lower slightly compared to Scenario One. The CMP supported conservation will not prevent, mitigate, or reverse the impacts of climate change-related stressors, as discussed for each category of the developed system, below. The anticipated changes, under Scenario Two, for each of important habitat stressors for the developed system are given in [Table 3](#).

Developed system—Open space: The current amount of open space on each island will see small increases ([Amidon and Reeves, 2018, unpublished data](#)). Conservation values regarding recreation and human access, invasive plants, animals and diseases, and wildfires will increase. Government agencies, non-profit organizations, and private landowners will increase enforcement of laws and regulations to protect open space from these five stressors, and possibly new efforts, laws, and regulations will be implemented. Altered hydrology and pollution and their effects on open space will not change. The effects of climate change-associated stressors such as drought may have a localized decrease because of conservation actions such as vegetation management through ungulate (axis deer) control and nonnative plant removal to improve water retention, even though air temperatures will moderately increase ([Table 4](#)). Resiliency of open space will slightly improve for the foreseeable future, due to lessened pressure from continued growth of impervious areas associated with low- to high-intensity development and some low-level management of stressors. Those islands currently with a smaller amount of open space (Moloka'i, O'ahu), relative to the islands of Lāna'i and Ni'ihau, may see more significant effects from stressors because the amount of open space is smaller initially, resulting in less redundancy and representation of this habitat (see [Figs. 1–4](#)). Although an analysis was not done specifically for Midway Atoll, we expect the amount of open space to remain the same or slightly increase because of better management; however, the possible rise in sea level at a future time period beyond 2035 may negate any increases in open space.

Developed system—Agriculture/cultivated land: Agricultural areas will continue to lose area ([Amidon and Reeves, 2018, unpublished data](#)); however, as conservation values increase, government agencies, non-profit organizations, and private landowners will continue to contribute resources to conserve these areas. Laws and regulations to protect agriculture/cultivated land from recreation and human access, invasive plants, animals and diseases, and wildfires will increase, and possibly new efforts, laws, and regulations will be implemented. Altered hydrology and pollution and its effects to agriculture/cultivated land will not change. The effects of climate change-associated stressors such as drought may have a localized decrease, even though temperatures will moderately increase ([Table 4](#)). Resiliency of agriculture/cultivated land will slightly improve for the foreseeable future, due to lessened pressure from continued growth of low- to high-intensity development and some low-level management of stressors. Those islands currently with a smaller amount of agricultural/cultivated land (Lāna'i, Kaho'olawe), relative to the islands of Kaua'i, Maui, and Hawai'i, may see more significant effects from stressors because the amount of agricultural/cultivated land is smaller initially, resulting in less redundancy and representation of this habitat (see [Figs. 1–4](#)).

Developed system—Low-intensity developed, medium-intensity developed, and high-intensity developed: Some development will occur but not at an increased rate, and there may be some redevelopment rather than newly created developed areas ([Amidon and Reeves, 2018, unpublished data](#)). Conservation values regarding recreation and human access, invasive plants, animals and diseases, and wildfires will increase. Government agencies, non-profit organizations, and private landowners will increase enforcement of laws and regulations to protect low-, medium-, and high-density developed habitat from stressors, and possibly new efforts, laws, and regulations will be implemented. Altered hydrology and pollution and their effects on the high-intensity developed system will not change. The effects of climate change-associated stressors such as drought may have a localized decrease because of conservation actions such as vegetation management through ungulate (axis deer) control and nonnative plant removal to improve water retention, even though air temperatures will moderately increase ([Table 4](#)). Resiliency of low- to high-intensity developed habitat will not change significantly. Those islands currently with the smallest amounts of low- to high-intensity developed habitat (Ni'ihau, Kaho'olawe) may not see significant increases of this habitat type because of their generally slower growth rate. The islands with a moderate amount of low- to high-intensity developed habitat (Lāna'i, Moloka'i, Hawai'i) may see a more significant increase in the amount of these categories, resulting in more redundancy and representation of this habitat (see [Figs. 1–4](#)). Although an analysis was not done specifically for Midway Atoll, we expect the amount of low- to high-intensity developed space to remain the same, keeping in mind the possible rise in sea level (and concurrent loss of low- to high-intensity developed habitat) at a future time period beyond 2035.

Future Scenario Three

There is a low to moderate decrease in conservation actions in the CMPs that substantially decreases the conservation management. Scenario Three has the second highest likelihood of occurring in the foreseeable future.

Summary: All natural resource management actions in the CMPs are set aside in deference to land use for development. With extensive localized management, some native species may persist in park-like settings or in areas where development is not possible.

Description: Scenario Three has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for development over the conservation of native landscapes. Areas that cannot support development become the only areas of free-living native species. An expanding human population requires increased land use for agriculture and development with no encumbrance from natural resource management. Biosecurity controls are significantly weakened in this Scenario leading to an increase in invasive species and new plant diseases. Combined, these factors will result in substantial increases in wildfire frequency, intensity, and extent. The substantial loss of CMP supported conservation may locally aggravate the impacts of climate change-related stressors. The anticipated changes under Scenario Three for each of the habitat stressors important to each category of the developed system are discussed below and are given in [Table 4](#).

Developed system—Open space: The current amount of open space on each island will decrease as a result of less enforcement of rules and regulations by government agencies, non-profit organizations, and private landowners ([Amidon and Reeves, 2018, unpublished data](#)). Conservation values will decrease resulting in a higher increase in recreation and human access, more invasive plants and animals, and more wildfires. Altered hydrology and pollution will have greater negative effects on open space as the pollutants from human use (construction) and agriculture are added to open space with fewer controls and without remediation. The effects of climate change such as higher temperatures and drought will also increase ([Table 4](#)). Resiliency of open space will decrease for the foreseeable future, due to increased pressure from continued growth of impervious areas associated with low-to high-intensity development and no management of stressors. Those islands currently with a smaller amount of open space (Moloka'i, O'ahu), relative to the islands of Lāna'i and Ni'ihau, will see greater effects of the negative impacts on open space, resulting in less redundancy and representation of this habitat (see [Figs. 1–4](#)). Although an analysis was not done specifically for Midway Atoll, we expect the amount of open space to decrease, resulting from the continued rise in sea level and continued loss of open space at a future time period beyond 2035.

Developed system—Agriculture/cultivated land: The current amount of agriculture/cultivated land on each island will decrease as a result of an increase in low-, medium-, and high-intensity development ([Amidon and Reeves, 2018, unpublished data](#)). Enforcement and creation of new laws and regulations to protect agriculture/cultivated land from recreation and human access, invasive plants, animals and diseases, and wildfires will decrease because of the increase in the effects of these stressors on the developed system with fewer control actions and no remediation. Altered hydrology and pollution and their effects on agriculture/cultivated land will increase. The effects of climate change such as higher temperatures and drought will also increase ([Table 4](#)). Resiliency of agriculture/cultivated land will decrease for the foreseeable future, due to increased pressure from continued growth of low- to high-intensity development and no management of stressors. Those islands currently with a smaller amount of agricultural/cultivated land (Lāna'i, Kaho'olawe), relative to the islands of Kaua'i, Maui, and Hawai'i, may see more significant effects from stressors because the amount of agricultural/cultivated land is smaller initially, resulting in less redundancy and representation of this habitat (see [Figs. 1–4](#)).

Developed system—Low-intensity developed, medium-intensity developed, and high-intensity developed: Low-intensity, medium-intensity, and high-intensity developed systems will increase in area ([Amidon and Reeves, 2018, unpublished data](#)). Conservation values decrease resulting in a higher increase in recreation and human access, more invasive plants and animals, and more wildfires, resulting in greater degradation of the developed system. Laws and biosecurity regulations and enforcement will decrease, exacerbating the effects of the increase of the human use, pollution, invasive species, and wildfires. Diseases carried by invasive plants and animals will also increase. Altered hydrology and pollution will have greater effects on developed habitat such as impacts from water extraction, and impacts from pollutants on the plants and animals in the developed system. The effects of climate change such as higher temperatures and drought will also increase. Changes to community planning will no longer be limited by conservation measures to control these stressors ([Table 4](#)). Resiliency of low- to high-intensity developed habitat will actually increase. Those islands currently with the smallest amounts of low- to high-intensity developed habitat (Ni'ihau, Kaho'olawe) may not see significant increases of this habitat type because of their generally slower growth rate. The islands with a moderate amount of low- to high-intensity developed habitat (Lāna'i, Moloka'i, Hawai'i) will see a significant increase in the amount of these categories, resulting in more redundancy and representation of this habitat (see [Figs. 1–4](#)). Although an analysis was not done specifically for Midway Atoll, we expect the amount of low- to high-intensity developed space to remain the same, resulting from the continued rise in sea level (and concurrent loss of low- to high-intensity developed habitat) at a future time period beyond 2035.

Future Scenario Four

There is a moderate to large increase in conservation actions in the CMPS that substantially improves conservation management.

Summary: An overt and robust, active, ongoing effort using moderate to major resources is made to identify and prioritize, with partners and stakeholders, the systems needed for conservation, and to actively restore and expand these systems. Scenario Four has the fourth most likelihood of occurring in the foreseeable future.

Description: A substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural habitats and biodiversity. Active and well-supported natural resource management begins to restore this habitat and ecosystem and expand their landscape areas. The needs of an expanding human population are addressed through more efficient land use governance based on redevelopment rather than development of new areas. Modern and novel agricultural

practices focus on those that do not affect existing natural areas or areas needed for native system restoration. Substantially improved biosecurity regulations decrease introductions of invasive species and plant disease. These improved land management actions result in decreased wildfire intensity, frequency, and extent. The substantial increase in CMP supported conservation may locally mitigate the effects of climate change-related stressors, but climate change is expected to continue. The anticipated changes, under Scenario 4, for each of the habitat stressors for each category of the developed system are discussed below and given in Table 4.

Developed system—Open space: The current amount of open space on each island will increase (Amidon and Reeves, 2018, unpublished data). Conservation values regarding recreation and human access, invasive plants, animals and diseases, and wildfires will be at their highest resulting in greater plant and animal diversity and greater water availability. Government agencies, non-profit organizations, and private landowners will increase enforcement of laws and regulations to protect open space from these five stressors, and new efforts, laws, and regulations will be implemented. Altered hydrology and pollution and their effects on open space will decrease. The effects of climate change-associated stressors such as drought may have a localized decrease, even though temperatures will moderately increase (Table 4). Resiliency of open space will improve for the foreseeable future, due to lessened pressure from growth of impervious areas associated with low-to high-intensity development and active management of stressors. Open space on all islands will see fewer effects from stressors resulting in more redundancy and representation of this system (see Figs. 1–4). Although an analysis was not done specifically for Midway Atoll, we expect the amount of open space to remain the same or slightly increase because of better management; however, the possible rise in sea level at a future time period beyond 2035 may negate any increases in open space.

Developed system—Agriculture/cultivated land: Agricultural areas will remain the same or possibly gain area (Amidon and Reeves, 2018, unpublished data). As conservation values increase, government agencies, non-profit organizations, and private landowners will continue to contribute resources to conserve these areas. Laws and regulations to protect agriculture/cultivated land from recreation and human access, invasive plants, animals and diseases, and wildfires will increase, and possibly new efforts, laws, and regulations will be implemented. Altered hydrology and pollution and its effects to agriculture/cultivated land will decrease. The effects of climate change-associated stressors such as drought may have a localized decrease, even though temperatures will moderately increase (Table 4). Resiliency of agriculture/cultivated land will improve for the foreseeable future, due to lessened pressure from continued growth of low- to high-intensity development and active management of stressors. Those islands currently with a smaller amount of agricultural/cultivated land (Lānaʻi, Kahoʻolawe), relative to the islands of Kauaʻi, Maui, and Hawaiʻi, may see more significant improvement because the amount of agricultural/cultivated land is smaller initially, resulting in more redundancy and representation of this system (see Figs. 1–4).

Developed system—Low-intensity developed, medium-intensity developed, and high-intensity developed: Low-intensity, medium-intensity, and high-intensity developed systems will decrease in area (Amidon and Reeves, 2018, unpublished data). Conservation values will increase resulting in managed recreation and human access, fewer invasive plants and animals, and fewer wildfires. Laws and biosecurity regulations and enforcement will increase, lessening the effects of the increase of human use, pollution, invasive species, and wildfires. Diseases carried by invasive plants and animals will also decrease. Altered hydrology and pollution will be better managed and have lesser effects on developed habitat. The effects of climate change-associated stressors such as drought may have a localized decrease, even though temperatures will moderately increase (Table 4). Changes to community planning will better implement conservation measures to control these stressors (Table 4). Resiliency of low- to high-intensity developed habitat will stay the same. Those islands currently with the smallest amounts of low- to high-intensity developed habitat (Niʻihau, Kahoʻolawe) may not see significant increases of this system type. The islands with a moderate amount of low- to high-intensity developed systems (Lānaʻi, Molokaʻi, Hawaiʻi) will see a more controlled increase in the amount of these categories, resulting in more redundancy and representation of these systems (see Figs. 1–4). Although an analysis was not done specifically for Midway Atoll, we expect the amount of low- to high-intensity developed space to remain the same, keeping in mind the possible rise in sea level (and concurrent loss of low- to high-intensity developed habitat) at a future time period beyond 2035.

Summary

Development, urbanization, and neglect of an ecological system can contribute to further loss of functional capacity of the system including loss of biodiversity. If management of stressors and other conservation actions are conducted, the loss can be kept at status quo, or possibly reversed, leading to an improvement in systems functions. Currently, for the foreseeable future (until 2035), we estimate that changes to the developed system in Hawaii will remain at status quo, with no significant gain or loss in functional capacity.

Introduction	263
What Is Sustainability Science?	263
References	265

Abstract

Given the scale of global change, we can fairly conclude that studying the biomes of our Earth must be accompanied by an investigation into why humans interact with biomes the way they do. Sustainability science is an emerging discipline addressing this need with distinct theories and lines of research while remaining deeply connected with related disciplines that link human and natural sciences such as conservation biology, anthropology, ecological economics, and sociology. In this article, we introduce and summarize how researchers from a wide variety of disciplines share work and ways of thinking that are critical for anyone studying human and social systems in both biomes and anthromes.

Introduction

What is the purpose, in an encyclopedia focused on biomes, of 25 articles on sustainability in concept and practice? Articles in the previous section focused on the idea of anthromes, or anthropogenic biomes. Those articles review the multitude of ways that human and social systems have shaped biomes via direct interaction with local, regional, and global landscapes and as a consequence of an increasing human population. Given the scale of these changes to local and global ecosystems, we can fairly conclude that studying the biomes of our Earth must be accompanied by an investigation into how and why humans have changed and used the natural resources within biomes and how our actions threaten the integrity, and perhaps the likelihood of continued persistence, of said biomes. At the same time, we should seek to understand the potential for humans to create positive change, emerge as leaders, and educate future generations.

Importantly, humans are not a monolithic group. Individuals and communities live in different places, have different histories and values, and response to different incentives. To that end, this section introduces you to some of the broader concepts, issues, and discussions that are occurring in disciplines outside of, but related to, scholarship in the natural sciences presented in the other volumes of this encyclopedia. In particular, we introduce you to the field of sustainability science and associated discourses from disciplines closely entwined with the work to create a sustainable society on our planet.

What Is Sustainability Science?

Sustainability science is an emerging discipline with its own theories and lines of research while remaining deeply connected with related disciplines that link human and natural sciences such as conservation biology, anthropology, ecological economics, and sociology (Clark, 2007; Kates, 2011). Sustainability scientists seek to link the study of natural and human systems with the explicit goal to create a world that can provide for all people while protecting natural resources and all species. Given the intimate and diverse connections between human and natural systems, any student or practitioner that seeks to protect biomes and associated flora and fauna must also understand the human and social systems. To understand, and ultimately influence, human behavior, laws and policies, and the paradigms that govern our decisions, we must seek to understand and integrate the knowledge that comes from diverse areas of study. In the articles below, researchers from a wide variety of disciplines share work and ways of thinking that are critical for anyone studying biomes or anthromes.

This section starts with an overview of two key theories that are at the heart of sustainability. Domazet et al. provide an overview of key models utilized by sustainability scientists, including the planetary boundaries and Doughnut Model. This latter model of economics was created by Kate Raworth as a way to visualize “social foundations of development to be achieved and biospheric boundaries not to be crossed.” Next, Quinn and Quinn explain the concept of Coupled Human-Natural Systems, a model that emerged largely from the field of ecology. They offer examples of key dynamics within CHANS that scientists and practitioners should be familiar with to engage in dynamic systems-thinking including: spatial and temporal scale, heterogeneity, and vulnerability within anthromes.

More narrowly focused on valuation theories, the next two articles consider how our current economic paradigms drive decision-making that pushes us past planetary boundaries, while also exploring alternative economic theories that can help create sustainable societies. and economic system evaluations. Domazet et al. overview the concept of degrowth, an economic framework that “re-orient economic activity away from material production” by decoupling capitalist economic growth with social well-being based

on the fundamental idea that there cannot be infinite economic growth on a finite planet. Extending this theme further, Collste challenges the “business as usual” model of economic growth by reviewing four alternative approaches to mainstream economics; Post-Keynesian economics, Critical Institutional Economics, Ecological Economics, and systems dynamics.

Much like current scholarship more broadly (e.g., [Chan et al., 2016](#)), the above authors all note how the value of anthromes, biomes, and natural resources is more than the economic value. Addressing this important theme, three authors help us examine the many different ways humans value the environment and our ever-changing and complicated relationships to nature. Allen provides an overview of how different working definitions of “values” and “valuation” from disciplines such as economics, anthropology, and philosophy have shaped assumptions about human behavior, and consequently, decisions and policies about conservation. Stone examines the role of ethics in deciding how and when to value anthromes by overviewing three ethical frameworks; descriptive moral psychology, traditional ethical theory, and environmental sustainability, that can be used to establish “ethical values for managing anthromes and principles for evaluating the human conduct that creates and modifies them.” Speitz critically examines the very idea of wilderness by looking at how views on the interconnection and/or separation of wilderness and humanity, and the resulting shifting purposes of conservation, has changed in the past century.

Sustainability science is ultimately about helping people create positive change to ensure a safe and healthy planet ([Raworth, 2017](#)). Therefore, much research and consideration are devoted to change-making and change-makers. These subsequent articles examine critical questions of *who* creates change and by looking at the roles of leaders ([Ferdig, 2007](#)). Ferdig disabuses us of the notion that a sustainability leader must be a charismatic visionary individual with global prominence and influence. She offers a definition of a sustainability leader as “anyone – regardless of background, social standing, expertise or positional power – who takes responsibility for understanding and generating workable solutions with others.” She offers 12 keys to practicing sustainability leadership. More narrowly, Burbach and Delozier look at a specific leadership role, the boundary spanner. A boundary spanner is someone who can “reach across organizational borders to build relationships, interconnections, and interdependencies in order to manage complex problems.” They use the increasing challenges within water management to examine the role that boundary spanners play in collaboration. Lastly, Breesawitz looks at how leaders can utilize communication tactics and conflict management to influence behavior among followers. He also looks at the interplay of leadership roles with environmental education. This section also offers three separate papers on educational issues (see below).

As noted above, it is not just who creates change but also how. The following five articles address *how* change is created by looking at the roles of leaders, interconnected disciplines, and organizations including aquariums and zoos, and cooperatives. Derezotes looks at the need for interdisciplinarity in sustainability and provides what he calls an ecobiopsychosocialspiritual approach. This article combines the insights of ecopsychology with social justice values by exploring the links between the well-being of anthromes and biomes with social and human well-being. Mann, Ballantyne, and Packer offer a look at the role of aquariums and zoos in promoting conservation and individual behavior change while also exploring the changing roles served by these essential organizations. Specific case studies of behavior change promotion are included such as; sustainable seafood, domestic cats, and the environmental impact of releasing balloons. Akanji proposes the cooperative as a principle unit for environmental management, arguing that cooperatives provide all members access to information, inclusive participation, and access to justice, which are necessary for holistic and sustainable environmental management. Lastly, an important article examines the need for, and current lack of, diversity and inclusion in conservation science and practice.

Next, three authors provide context for examining *how* change is created as well as barriers to achieving sustainable practices in light of uncertainty and complexity in both human and natural systems. First Bamberg and Schulte overview central questions asked by environmental psychologists and utilize compelling research within another sub-discipline, health psychology, to examine five overarching themes of processes present during behavior change: motives, self-regulation, resources, habits, and environmental/social influences. They also discuss the practical implications of said research for helping people adopt a more sustainable lifestyle. One frequently discussed aspect of behavior change is associated with farming and food systems. Indeed, when individuals begin to consider how to live a more sustainable lifestyle, one of the first things they question is their diet. Bignet et al. review studies on metrics that define and/or assess the health and environmental impacts of different dietary choices. Lastly, the concept of “sense of place” is an important theory utilized by sustainability science researchers. Knapp explores how sense of place shapes and is, in turn, shaped by anthromes. She then examines how sense of place may influence responsiveness to climate change. While sense of place has been primarily considered a positive motivator for environmental conservation, Knapp shows that it is sense of place that may lead to “resistance, slow response, active adaptation or transformed sense of place” when confronting climate change. This is a key point in many topics where our initial perception of an idea may need to change in the face of more information or nuance.

Scientists are often criticized for an inability to effectively communicate research to mass audiences, contributing to low levels of scientific understanding and therefore low levels of support for behavior change and environmental policies by the public ([Lindenfeld et al., 2012](#)). Five authors provide perspectives on different areas where communication of sustainability is important including on social media, by individuals working on conservation projects, and in agriculture. Reilly looks at the application of social media for sustainability communication by individuals, corporations, and public entities. She examines critical concerns of online communication for sustainability including greenwashing and the challenges of measuring sustainability performance. Sklair and Boykoff examine how anthromes have appeared in mass media coverage of climate change and which ideas of anthromes have appeared in mass media coverage of the Anthropocene. They show how media coverage of “anthro” and “climate change” has increased in popular news media in the last decade. The authors then examine how anthromes such as urban cities, croplands, rangelands, and forests are discussed in regards to “the anthropocene”.

Briggs looks at the challenges faced in communicating science to a broad audience including use of jargon and the lack of science literacy among the general populace. She first summarized the history of science communication and then provides an overview of methods used to successfully communicate science and conservation projects. Briese looks specifically at science communication within agriculture and the role of extension scientists and public and private crop advisors play in communicating science to farmers. He examines how individuals in these roles become “trusted partners” to deliver the latest information and research to the men and women working on the farm. Lastly, to address the need for better communication, Bernier explores a deep human instinct that can be used in communicating sustainability: storytelling. He offers specifics on creating a “sustainability story” that is compelling to the reader, communicates knowledge, and inspires action. He concludes with a list of sustainability story examples.

One of the most important topics for understanding how to create a sustainable planet is the role of education (Tilbury, 1995). Below are three unique articles that examine how education can contribute to peoples’ understanding of conservation and sustainability in biomes and anthromes. The first article looks at the broader role for education while the following papers look specifically at those who are training to work in conservation. Powell, Smith, and Brown begin their article that focuses on the importance of training wildlife biologists to work in anthromes and on private lands with a critique of current higher education training that focuses on public lands management. They then offer a case study of a modification to the learning objectives for a fisheries and wildlife degree program at the university level and offer suggestions to enhance efforts to train wildlife biologists to work in the arena of anthromes and private land. Davis shares principles of education for sustainability including: enabling learners to see issues and solutions through critical thinking and developing agency and transformative capabilities. She then offers case studies of how education for sustainability is being applied across a range of educational contexts, from K12 through higher education. Last, Wood provides a personal narrative as a young conservationist training to protect nature in a time of increased and rapid anthropogenic change. She documents three key considerations as conservation moves further into the 21st century; exercising flexibility in where conservation occurs, more openness to what a conservationist may look like, consideration of a wide range of necessary skills for innovative problem-solving, understanding the importance of experiences in influencing behaviors, and engaging non-scientific audiences.

While by no means comprehensive, the articles above provide an overview of intersectionality and interdisciplinary considerations necessary for today and tomorrow’s sustainability scientists, conservation biologists, and practitioners seeking to protect our environment while creating a safe home for humans. Each article can be stand-alone and or supplement biology and ecology classrooms and discussions. Our aim here was to offer a wide range of considerations and discussion points to augment the study of the world’s biomes. Every student, faculty member, and even citizen will need to have a basic understanding of how sustainability functions in theory and practice as we collectively strive to create a sustainable future.

Abstract

Systems thinking is a way of looking at the world to understand how individuals, populations, communities, and institutions interact beyond their distinct boundaries. Coupled human and natural systems (CHANS) has emerged as one framework to better understand the connections within and between systems often looked at separately. Researchers and practitioners are interested in how these couplings function to move along a pathway toward (or away from) a sustainable future. In this article we review key elements of CHANS. These elements are applied to examples from human, natural, and coupled systems including agriculture, conservation, lakes, the human body, fire, and climate change. We end with a case study to link anthromes and CHANS.

Introduction

Systems thinking is a way of looking at the world to understand how individuals, populations, communities, and institutions interact beyond their distinct boundaries. For example, systems thinkers look at how the conservation of wildlife predators affect prey populations (Carter et al., 2014) or how private land owners affect biodiversity conservation (Quinn and Wood, 2017). Coupled human and natural systems (CHANS) has emerged as one framework (alongside social-ecological systems and human-environment systems) to better understand the connections within and between systems often looked at separately. Central to this concept is how human systems and natural systems interact; i.e., how they are coupled. CHANS is the explicit acknowledgment of a two-way interaction where the condition of natural systems are shaped by human decisions and that the condition of human systems is shaped by natural processes (Fig. 1). In addition, researchers and practitioners are interested in how these couplings function to move along a pathway toward (or away from) a sustainable future. For example, systems thinkers using a CHANS concept will ask how the loss of pollinators in agricultural systems is affected by practices farmers use on their farm and, also, how the abundance or absence of pollinators affects the yields that a farmer can produce in a year. Formalized by Liu et al. (2007a,b), the concept of CHANS has been applied by a large and diverse network of scholars (<http://chans-net.org/>) to frame examinations of how humans and the environment interact. Scholarship in CHANS has recently been described as “complex, dynamic, interconnected” (Ferraro et al., 2019). This focus on complexity is in direct contrast to how science is most frequently conducted with a focus on reductionism, isolation, and disciplinary silos.

In this article, we briefly review core elements of coupled human and natural systems (CHANS), providing examples from within and between human and natural systems to discuss how thinking in systems provides a deeper understanding of our current state in the world, how things came to be the way they are, and how we can be intentional in moving forward as we create a sustainable planet. Then as a brief case study, we link CHANS and anthromes to explore the theme of this article as part of the broader theme of Volume 5 of this Encyclopedia.

Identification of Human and Natural Systems

The term system can be applied to a wide variety of organized units. Broadly, a *system* is a collection of similar or interacting parts. Meadows (2008) describes a system as “a set of things interconnected in such a way that they produce their own pattern of behavior over time.” When utilizing a CHANS lens to examine a sustainability issue, it is often helpful to start with a list of individual human and natural systems. In Fig. 2, systems associated with private land conservation such as landowners, migratory bird species, or

Fig. 1 CHANS model from the US National Science Foundation (NSF). Key elements suggested by NSF are “(1) the dynamics within one or more natural systems (2) the dynamics within one or more human systems (3) the processes through which the natural systems affect human systems (4) the processes through which the human systems affect the natural systems.”

Fig. 2 A list of human and natural systems associated with private land conservation sorted by spatial scale. Reprinted with permission from Quinn JE and Wood JM (2017) Application of a coupled human natural system framework to organize and frame challenges and opportunities for biodiversity conservation on private lands. *Ecology and Society* 22(1): 39.

national farm policy are listed. Then one can examine how each of these systems interact with and impact the others (the focus of the rest of this article). For example, landowners may influence migratory bird species through their choice to provide suitable habitat or not. Whether or not a landowner can afford to, or is willing to, leave habitat available for birds may be influenced by national farm policies. These interactions, among many others not listed here, will determine the health of migratory bird species.

Scale

When you have an assortment of systems identified, one way they can be organized is by different *scales*, including but not limited to, spatial, temporal, biological, and social. Human systems exist from small scale (such as an individual making the decision to recycle) through to large scales (such as international organizations such as the United Nations FAO including global agricultural policy). Natural systems can exist from a declining population of pollinators in a restored Iowa prairie to the Earth's global scale carbon cycle. Considering scale can help organize the complexity of different systems. Indeed, Simon Levin wrote in 1992 that "scale... is the fundamental conceptual problem in ecology if not in all of science... unifying population biology and ecosystem science, and marrying basic and applied ecology."

One helpful way to visualize variations across scale is with a stommel diagram. Stommel diagrams are one tool for organizing systems across scales that has been used in different disciplines (reviewed in [Peterson, 2010](#)). The example of a *stommel diagram* below from [Gordon et al. \(2008\)](#) shows the time and spatial scale over which shifts or patterns occur in different systems. Starting a systems analysis by organizing the relevant systems by scale can be a very effective way to see how different systems relate ([Fig. 3](#)).

Another way that systems are often organized across scales is as *nested systems* ([Liu et al., 2007a,b](#)). The concept of nested systems explains that systems exist within other systems. An easy way to understand this is to consider a smaller system, the human body. Humans have many systems such as digestive, reproductive, respiratory, and circulatory. All of these systems are nested within a larger system; the individual. The same goes for human systems, natural systems, and CHANS. A tree is a system itself but is nested within a population of trees, which is nested in a community that is a forest ecosystem. A university is a system but is nested with the larger system of higher education, which is nested in a broader human community. Likewise, the university campus and all the students living and studying there are also nested in the larger natural ecosystem of the biome the university was built within.

What is key for CHANS is connecting the human and natural systems. For example, people growing food are nested within larger systems of government and economic policy that influence when and how people can access resources. The same farm growing food is nested within broader climate patterns that determine what crops can be grown (e.g., coffee in the tropical anthromes and wheat in temperate cropland anthrome). As noted above, how a person manages land for food production affects the quality of the natural system. For example, excess pollution in a large watershed can impact the fish in a stream nested in that watershed. Other examples include how cities respond to changes in precipitation patterns and flooding due to climate change, how biodiversity conservation in protected areas affects local residents, and how cultural norms around food and fishing impact local fish populations through sustainable management or over-fishing. Indeed, many of these systems are discussed throughout this volume for those interested in learning more.

Similar to how systems are nested, systems can be linked over longer distances. *Telecoupling* refers to links between humans and nature through space; from local to global links. For example, when someone purchases a computer that contains tin or tungsten that was mined in Africa and parts that were assembled in China and shipped to France, that person is linked through space with natural systems that provide these materials from far away as well as to all of the people who were involved in the mining, processing, production, transportation, and retail of said computer. Farming and food systems have many telecoupled elements including distribution of food, sourcing of synthetic inputs, and spread of pollution. For example, [Rey and Huettmann \(2019\)](#) recently modeled the telecoupling of fisheries in Patagonia ([Fig. 4](#)).

Legacy Effects and Time Lags

Two essential elements of understanding temporal scale within systems are *legacy effects* and *time lags*. The temporal scale recognizes that human and natural systems interact through time. Time lags and legacy effects occur because the feedbacks or couplings between systems are not always immediate. Humans are interacting with an environment billions of years in the making by our use of fossil fuels and our actions today will have consequences far into the future. For example, within human systems, we do not see the results of investment in preschool education until years later when examining well-being and attainment outcomes for children who received early schooling years before. These same children's perception of the value of nature later as adults is influenced by how much time they spent in nature as a child (Holt et al., 2019).

Another example is the impact on current climate patterns from the Industrial Revolution. Manufacturing and industry increased in the late 1700s. As a consequence, the amount of carbon dioxide and other pollutants in the atmosphere increased. One immediate effect of this at a local scale was poor air quality (e.g., the London Fog). However, many of the effects of this pollution were not seen immediately. One of these was climate change. There was a time lag on the impacts of increased carbon dioxide in the atmosphere. Thus the increases in global surface temperature we are seeing today are a legacy effect of historical pollution. Indeed, when we examine the current state of any system, it is the result of all actions that came before; the current state of a system is actually a legacy. The current state of the health of your body is a legacy of all of the choices you have made until today (amount of sleep, the food you ate) as well as factors beyond your personal control (genetics and socioeconomic status). Current low household wealth among African Americans in the United States is a legacy of slavery, segregation, and racist economic policies in deciding who received home loans and who did not. Looking at the legacy of the past can provide important insight and unexpected conclusions about the current state of a system. For example, the Scottish Highlands and English Lake District are celebrated for the grassy slopes and an abundance of sheep. However, this pastoral landscape is heavily modified by human intervention in the past, including but limited to a legacy of timber clearing by the Romans, English land ownership policies, and recent subsidization of grazing (Hobbs, 2009).

We can see that much of the difference between a time lag and legacy effect is based on the time frame that you are referencing from. A coupling is best framed as a legacy if you are looking to the past. A time lag may be more valuable if you are looking forward.

Heterogeneity

Part of the complexity of understanding interactions within and between systems is *heterogeneity*. The prefix "hetero" means "different." Heterogeneity is the idea that couplings between human and natural systems and subsequent outcomes or patterns are different within and across systems, place, or time. Humans affect and are affected by, natural systems in very different ways. For example, people in highly developed countries have a greater indirect effect upon the environment through their creation of carbon emissions than do people in less developed countries. Yet, people in poverty will experience the consequences of high carbon emissions (climate change) in very different ways than wealthier populations. A person who relies upon subsistence crops to feed their family will be more immediately and more seriously impacted by drought than someone who may not be able to purchase blueberries at the grocery store because of seasonal drought in another hemisphere but still has the option to purchase

Fig. 5 Heterogeneity in agricultural landscapes. Clockwise from the top left—Minnesota, USA; Kansas USA, northwest Germany, Brazil, Thailand, and Bolivia. Image from NASA. Figure available from: <https://earthobservatory.nasa.gov/images/6605/agricultural-patterns>

strawberries from down the road. Another example is how people living in coastal regions will experience climate change effects such as rising sea levels while people in other areas will be affected by wildfires.

Another way to look at heterogeneity comes from the field of landscape ecology. From this perspective, heterogeneity is described as the variation in the spatial pattern and configuration of different land use and land cover types (e.g., [Fahrig et al., 2011](#)). The patterns of land use and land cover that we see when we look at satellite images show how both natural and human systems create heterogeneity or diversity in land use and land cover. This composite image from NASA ([Fig. 5](#)) of different agricultural landscapes shows heterogeneity within each photo (different size fields, different intensities of green). Between these images of farmland, we also see heterogeneity between different agricultural systems. For example, the image on the top right of cornfields in Minnesota looks very different than the rice fields from Thailand in the bottom middle. These spatial patterns are a combined outcome of both human and natural processes including human drivers of habitat fragmentation, policy, and economic incentives and natural drivers of precipitation, soil type, and potential vegetation.

Nonlinear Dynamics, Thresholds, and Catastrophic Change

Thresholds are transition points between states within a system ([Fig. 6B](#)). When a threshold is reached, a system will change rapidly. This is in contrast to a linear change ([Fig. 6A](#)) where a system state changes gradually as the conditions change (i.e., the metaphor of the frog in the pan with warmed until boiling). Thresholds are important to watch for because of the suddenness of the change and the subsequent impacts on human and natural systems. Imagine a lake system that is catching nitrogen run-off from surrounding urban yards. For a while, perhaps even years, the lake may support plant and animal life despite the increased fertilizer applied to keep yards green. However, there is a limit to the amount of fertilizer that the lake can absorb before an algae bloom occurs. Subsequently, the algae bloom affects the availability of oxygen supplies and, seemingly suddenly, the lake has crossed a threshold from a place that can support life to one that cannot. Although the nitrogen has been building up in the lake for years, it's a sudden shift

Fig. 6 Models of (A) linear, (B) threshold, and (C) catastrophic change. Modified from Scheffer M, Carpenter S, Foley JA, Folke C, and Walker B (2001) Catastrophic shifts in ecosystems. *Nature* 413(supplement 6856): 591–596.

from one state to another (life-supporting to non-life supporting) that seemed to happen quickly. This seemingly-rapid shift is explained because many thresholds are non-linear; i.e., we do not see a gradual and constant change in a system. Instead, we experience rapid change.

Like a threshold change, a *catastrophic* change (Fig. 6C) results in a rapid shift in a system state. However, unlike a simple threshold change, the catastrophic change results in *hysteresis* where multiple system states may exist under the same conditions. As a consequence, for a system to recover to its former state (for example, the life-supporting lake above), the system needs to return to a condition different from the tipping point of the initial change. Most frequently this necessary condition for recovery requires difficult, expensive, and time-consuming restoration to conditions far beyond the last state (i.e., in a lake, it is not enough to merely remove the last ounce of added fertilizer that tipped the system, the lake may have to be completely dredged to remove all pollution) then the tipping point of the threshold of initial change. Another way to think about a catastrophic change is to think of the two alternative states as basins of attraction (Fig. 8). In this figure, the two points lowest points on the lines, or basins of attraction, represent alternative stable states. How difficult it is for a system to cross the threshold can be judged by how steep the walls of the basin are. Specifically, the steeper and taller the basin the more resilient the system is.

Thresholds and phase shifts exist within many coupled human and natural systems. The lake example above is an example of a local scale. On a global scale, the planetary boundaries described by Steffen et al. (2015) are suggested global thresholds for different changes to the planetary earth processes. The difficult part for scientists and policymakers is that there is much *uncertainty* (Fig. 7) in exactly what the threshold is for many systems. When there is uncertainty it is difficult to predict when an event will occur and communicate the need for change when a system appears healthy.

Fig. 7 Uncertainty in exact point of a threshold of change. Reprinted with permission from Rockstrom J et al. Planetary boundaries: Exploring the safe operating space for humanity. *Ecology and Society* 14(2): 32. [online] URL: <http://www.ecologyandsociety.org/vol14/iss2/art32/>.

Vulnerability, Resilience, and Resistance

Liu et al. (2007a,b) define vulnerability in CHANS as “the degree to which systems are likely to experience harm due to changes in internal and external variables.” When a system is *vulnerable*, it is sensitive to being changed. All CHANS systems and subsystems are more or less vulnerable and have the potential to be changed due to human factors, environmental factors, or a combination of both. The opposite of vulnerability is *resiliency*. A system is resilient if it can recover from difficult conditions. Liu et al. (2007a,b) define resilience as “the capability to retain similar structures and functioning after disturbances for continuous development.” *Resistance* is the ability of a system to withstand change. Though resilience and resistance concepts are similar, it is often valuable to differentiate, which we do in the explanation below.

One way to visually represent vulnerability, resilience, and resistance is seen in Fig. 8 as a series of basins of attraction and a rolling ball. Any system can be represented by the ball; this can be a small system such as a lake or a human or a planet-level system such as atmospheric carbon or international governmental treaties. Each system, in its current state, rests in a basin of attraction. Each system has the potential to be moved into a second basin; the location of the dotted circles. If a system experiences “changes in internal or external variables”; a hurricane, a recession, pollution, disease, war, etc. it is being pushed “up” a slope toward a change, potentially rolling into a new basin, which represents a new state.

Vulnerability: If a system is more vulnerable to change, or less resilient, its basin would be drawn as less “deep.” In Fig. 8, System C, is more vulnerable than Systems A and B. Basin C is shallow and therefore System C is more vulnerable to going into a different state. Systems A and B *could* be pushed into a different state, but it would take much larger changes in internal or external variables. The factors that make a system more or less vulnerable will be distinct for each system and each CHANS interaction.

Resilience: The resilience of a system is its ability to *recover* from changes in variables to remain in a stable state. In the figure, this is represented by the depth of the basin of attraction. If the system rests in a deep basin and is pushed by a change in variables up the slope, it will be more likely to “roll” back down into its basin; is more resilient. Systems A and B are more resilient than System C. Of course, it is possible to push any system into a new state given the strength of changes in variables, yet Systems A and B are less likely to be pushed over the *threshold*. We often talk about resilience as a good thing, it is important to note that a system can also be resilient in a poor or unhealthy state.

Resistance: The resistance of a system is its ability to avoid or withstand any change and remain in a stable state. In the figure, this is represented by the steepness of the slope of the basin. System A has the greatest resistance due to the steepness of its slope.

Human systems, natural systems, and CHANS all experience vulnerability, resilience, and resistance. An adult human with a strong immune system is more resistant to catching the flu than a frail elderly person. Even if they do catch the virus, they would be more resilient to recovering from the challenges than an elderly adult with a weakened immune system who would be less resistant to catching the flu and less resilient to recover if they got sick. An ecosystem with greater species richness, which is a greater number of different species, is more resistant to invasive species because more ecological niches are already filled. Tilman et al. (2006) have shown that an ecosystem is more vulnerable to change if it has lower biodiversity. Greater biodiversity provides resilience because it allows an ecosystem to recover if it experiences a change in variables such as disease, drought, fire, deforestation, etc.

It is particularly important for researchers and practitioners to understand these dynamics within CHANS. In the last decade, California, in the United States, and more recently Australia have experienced increasingly strong and deadly forest fires due to changes in internal and external variables in both human and natural elements of the larger system. Human actions and policies have made both human and natural systems more vulnerable to fires. Forest ecosystems have been managed to suppress the fire, resulting in a build-up of flammable biomass which makes forests less resistant to sparks that can start fires. Simultaneously, humans have continued to build homes within and adjacent to fire-vulnerable areas, putting their homes and themselves at

Fig. 8 Model of variation in vulnerability, resilience, and, resistance.

risk. Human and wildlife communities are now more vulnerable to the consequences of forest fires. Forests that burn may recover through ecological succession, but human communities that do not have financial and governmental resources to rebuild are less resilient to recovery and some communities that have burned may never be rebuilt.

Feedback Loops

Feedback loops are ways that systems regulate themselves. Feedback loops can be reinforcing or balancing (sometimes called positive and negative, though those terms often confuse people so we will use reinforcing and balancing here). Reinforcing feedback loops continue to grow a stock within a system or cause something small to increase in size or magnitude. Consider a small ball of snow rolled down a mountain. The snowball (a stock of snow) continues to grow as it rolls. As it gathers more snow and grows, it has a larger surface area that can, in turn, gather even more snow until a giant avalanche is created! An example of a reinforcing feedback loop from human systems is a bank account that gains interest each quarter. As the size of the savings account grows, each quarter it will earn more interest and increase exponentially. Environmentally, increased earth surface temperature increases evaporation from the oceans, resulting in greater water vapor in the atmosphere, increasing greenhouse gasses which then, in turn, again increases the Earth's surface temperature.

CHANS researchers focus on reinforcing loops that influence how human and natural systems interact. Population growth, of humans and all other species, is a key reinforcing feedback loop. Although we may all want a never-ending increase in our savings account due to interest earned, often, if a reinforcing feedback loop is never checked, disaster would quickly ensue. This is where balancing feedback loops come into play. An example from natural systems is the unchecked growth of invasive species. The potential exponential growth of the invasive species allows its population to continue to expand and outcompete native species.

A balancing feedback loop is one in which a system is kept within certain boundaries. Your body temperature is an easy example. If you get too hot, your body has the balancing feedback loop of sweating to cool you down. If you get too cold, your body will shiver to warm you up; thus keeping you within a few acceptable degrees of body temperature. Balancing feedback loops keep a system from crossing a threshold into another state; i.e., in regard to your body temperature it keeps you in the state of being alive. Balancing feedback loops are also in play regarding population growth. Births are a reinforcing feedback loop that, if left unchecked, would never end. Death ensures a balancing feedback that keeps a population within an acceptable range for a given ecosystem. This is why predation by wolves on deer populations is essential to keep deer or any grazer numbers from getting so large that they exhaust their food reserves and starve. Within CHANS, when scientists and policy-makers see reinforcing feedback loops occurring that can damage people or the environment, policies can be implemented to change (or balance) behavior. Indeed, management of large carnivores is a key feedback between human natural systems. [Estes et al. \(2011\)](#) describe how the loss of large predators globally is affecting human and natural systems. However, the complexity of human values associated with predators adds complexity to any suggested simple solution (e.g., [Expósito-Granados et al., 2019](#)).

Surprises

The concept of surprises is important for scientists and practitioners to be aware of even if they cannot be predicted. People and nature do not always react in the way we assume they will. For example, when a major donor gives funds to protect a forest, this can create an unexpected opportunity for conservation in a region. And yet, local residents may be unsupportive of such conservation for seemingly surprising reasons ([Quinn and Wood, 2017](#)). Likewise, a single unpredicted but impactful environmental event can have surprising effects on an ecosystem. For example, [Philpott et al. \(2008\)](#) described how a hurricane damaged areas of coffee plantations and that decreased vegetation complexity on the farm increased impact of landslides after the hurricane. Farmers in certain areas may be prepared for hurricanes, but unprepared and surprised by the after-effects of such events. Therefore, it is essential to recognize and build plans for surprises, good or bad.

Using CHANS to Describe and Better Understand Anthromes

At local, regional, and global scales, land use and land cover change is a clear reflection of the coupling between natural systems and human systems. One global classification of land cover is anthromes. Anthromes, or anthropogenic biomes, characterize at a global scale, ecological patterns of land use and land cover created by sustained direct human interaction with ecosystems ([Ellis and Ramankutty, 2008](#)). Anthromes fall along gradients of land-use intensity and population density, incorporating natural, used, and novel ecosystems to classify areas as Used (including dense settlements, villages, croplands, and rangelands), Seminal, and Wild ([Ellis et al., 2010](#)).

Indeed, anthromes embody many elements of CHANS and can be used to frame conservation actions in anthromes ([Martin et al., 2014](#)). Anthromes are classified at a global spatial *scale*, but can be used to consider regional scale patterns. Anthromes show the *heterogeneity* of land use and land cover patterns missing when we define landscapes as biomes devoid of human interactions. They also show the *feedbacks* between human and natural systems that are an essential component of understanding complex systems. For example, the shifting croplands of the central Great Plains USA ([Fig. 9, Quinn et al., 2017](#)) show how

Fig. 9 Threshold shift in extent of cropland and rangeland anthromes in 1900 in the central United States' Great Plains. Reprinted with permission from Quinn JE Awada T Trindade F Fulginiti L and Perrin R (2017) Combining habitat loss and agricultural intensification improves our understanding of drivers of change in avian abundance in a North American cropland anthrome. *Ecology and Evolution* 7(3): 803–814.

expanding farming systems incentivize increased production and subsequent expansion. Historical anthromes provide an opportunity to consider how current systems might be a *legacy* of past decisions. They can also help frame current conservation challenges when a legacy of past land use is considered. For example, the 400-year legacy of agriculture in Europe currently dictates or at least drives many conservation issues, particularly the focus on farmland birds. The change in anthromes over time highlights the *non-linear dynamics* of land use and land cover change. For example, as seen in Fig. 9, the rapid loss of wilderness and subsequent increases in cropland and rangeland across the central United States between 1800 and 1900 (Quinn et al., 2017). In conclusion, both anthromes and coupled human and natural systems provide a way to better describe, model, and understand complex patterns that link human and natural systems.

Abstract

Due to the concern that achieving human wellbeing through material development is “costing the Earth,” a mental model was developed to show in a single image the aspiration of social foundations of development to be achieved and biospheric boundaries not to be crossed. Anthromes analysis, combined with the cultural imperative of maintenance of global sustainability through coordinated transformation of social metabolism and its environmental impact, makes nation states the immediately available units of sustainability modeling. In this century humans must meet their needs equitably within the biophysical means of the planet. A downscaling of planetary boundaries and social wellbeing foundations (thresholds) to national level through calculations of the impacts and attainments of nation states’ socioeconomic activities makes the doughnut model a conceptual tool bringing sustainability closer to political and organizational impact. To visualize the scale and the possible pathways for the transformation of national and global sociometabolic practices in the 21st century within the “degrowth doughnut” includes the boundaries and thresholds in three domains: cultural, socioeconomic, and biophysical. This way it aims to avoid the conceptually paralyzing trade-off between exclusively biophysical boundaries and exclusively social thresholds of the other doughnut models. Understanding that excesses and shortfalls of current and foreseeable socio-metabolic practices exist in cultural, socioeconomic, and biophysical aspects of nations’ social metabolism allows us to build on nations’ sustainability potentials. The aim of the model and its visual tool is to inform their populations about the direction and scale of the change strategies that they could adopt to contribute to the global effort of maintaining the planetary population within the safe and just operating space of the doughnut under known advantages and constraints of the 21st century.

Planet Earth as a Mosaic of Anthromes

Human influence on the terrestrial biosphere is so pervasive (Barnosky et al., 2012; Kastner et al., 2015; Kolbert, 2014; Steffen et al., 2004; Vitousek et al., 1997; Wilkinson and McElroy, 2007) that the present has been proposed as an entirely new geological epoch, the Anthropocene (Crutzen and Stoermer, 2000). Criticism of the equalizing effect of this term on all human communities (Bonnet and Fresco, 2016; Moore, 2016) warns that this influence is not effected equally by all humans based on their biological and ecological essence, but through human cultural and political institutions (Wainwright and Mann, 2018) with inherent inequalities of benefits and burdens. Anthromes, or “anthropogenic biomes,” present a view of the terrestrial biosphere that takes into account the “sustained direct human interaction with ecosystems” (Ellis and Ramankutty, 2008), providing an alternative global framework for ecological understanding of the terrestrial biosphere as it exists today. The anthromes provide a patchwork of varying intensities of human interaction with the biosphere and denote inequalities in historic and present modifications to the biomes. However, they remain silent about the sustainability of these modifications and their connections to other parts of the patchwork through human culturally constructed institutions.

Anthromes framework recognizes vast differences in human presence in different anthrome types, forming heterogeneous landscape mosaics. This heterogeneity stems primarily from anthropogenic motivations for landscape modification, conditioned by natural geophysical variations of terrestrial biomes. For example, urban activity or agricultural production, in and of themselves, say nothing about the purpose, benefits, and possible future developments of said ecosystem interactions. The anthropogenic motivations, on the other hand, stem from the human cultural constructs that are socio-economic activity and socio-culturally diffused aspirations and values. Strategies for the utilization and modification of the biosphere are, from a planetary perspective, most readily expressed through internationally recognized states (Cudworth et al., 2007).

Anthromes analysis combined with the cultural imperative of maintaining global sustainability makes states the anthromic units of sustainability modeling. Sovereign states become pieces of a heterogeneous global mosaic, and they combine landscape biophysical conditions and the anthropogenic enhancement and re-creation of the said landscape. Furthermore, their social reproduction practices (Bhattacharya, 2017) included in the degrowth doughnut add further understanding of the particular units' contribution to global (un)sustainability. A better understanding of the sustainability potentials and challenges of these states lays the groundwork for an eventual (constructive) understanding of the anthropogenic biomes that will guide interactions between humanity and nature towards preservation, diversity and fecundity rather than extinction. Having taken the political and economic state as a provisional unit of analysis, including ecosystem interactions and social development strategies, the degrowth doughnut model presents a holistic framework in which to view its fair sustainability potential.

Safe and Just Operating Space (SJS) Between Planetary Biophysical Boundaries and Sociometabolic Development Thresholds

In the concern that achieving human wellbeing through material development is “costing the Earth,” a mental model was developed of the tradeoff between the social thresholds to be achieved and the biospheric boundaries not to be crossed (Raworth, 2012). On the inner side of the ring, below the social foundation, lie the shortfalls in providing for average human wellbeing. On the outer side, above the ecological ceiling, lie the excesses of pressure, overshoots, on the planetary life and regenerative systems. Between the two sets of boundaries is the doughnut shaped ecologically safe and socially just abstract space for humanity in the 21st century (Raworth, 2017). Perhaps without meaning to, the SJS model provided a visualization of the *efficiency* of human development (affected also by its outreach, or whom the development was to extend to), whereas we shall be presenting the *sufficiency* of degrowth strategies below.

The biophysical boundaries aspect originates from the planetary boundaries visualization quantifying civilization's impacts on the overall planetary biosphere within a finite circular limit (Rockström et al., 2009; Steffen et al., 2015). These connect to the regions', nations', and communities' unequal contributions to the impacts (and the unequal extraction of the associated benefits) through the estimation of the footprint indicators for different biophysical processes associated with various socio-economic practices (Hoekstra and Wiedmann, 2014). The first step in the construction of the doughnut model, both as a mental model of human interaction with the biosphere and as a visualization, is to combine the boundaries and footprint approaches through the downscaling and calculation of the impacts of socioeconomic activities in national anthromic mosaics (O'Neill et al., 2018).

There are, of course, a variety of ways that the downscaling of planetary boundaries to a unit of nation state can be performed. By, for example, understanding regional environmental limits and the sustainability aspirations of its human population or by distributing a share of each planetary boundary among the states based on some allocation formula. One such allocation formula, simple enough to understand and without discrepancies between climatic specificities, resource availability, and historically differentiated responsibilities (Baer, 2013; Shue, 1999), is the per capita biophysical boundary approach, distributing shares based on current population. The aforementioned discrepancies with the allocation formula, and others like them, are important for resource management and fair responsibility apportionment (O'Neill et al., 2018). However, for the initial conceptualization of a new model and the simplicity of its broad application across orders of magnitude, a straightforward per capita downscaling of boundaries is justified.

As the challenge for a reflective global human population in the 21st century is to meet its needs within the biophysical means of the planet, boundaries along the outer rim are supplemented by the desirable social foundations to be distributed along the inner rim, thus converting the circle of boundaries into a doughnut ring made up of two belts of social foundations and biophysical boundaries (Fig. 2). Again, the definition of the threshold associated with any given foundation, its selection, and its measurement can follow different methodologies, from human needs theory to the politically set Sustainable Development Goals to social and cultural policies associated with degrowth of material throughput (Doyal and Gough, 1991; Kallis, 2018; Raworth, 2017).

Downscaling the fairshare burden of planetary resource use and pollution, and equitable development attainment gives a national doughnut visualization (Fig. 3; O'Neill et al., 2018). One such iteration for individual states presents 11 social objectives (or “foundations”) alongside the nine scaled-down planetary boundaries. A single graphical image quantifies the level of biophysical resource use associated with meeting residents' basic needs. This model modifies the original planetary boundaries structure (Fig. 1) to include ecological footprint and material footprint on the outer rim, along with nine needs satisfiers (nutrition, sanitation, income, access to electricity, education, social support, income equality, quality of democratic institutions, and employment) and two measures of human wellbeing (self-reported life satisfaction and healthy life expectancy) (Fig. 3; O'Neill et al., 2018).

Even in this framework, no direct causal link is implied between the level of resource use and social outcomes, focusing instead on conceptualization of interdependence between social outcomes and “healthy, functioning ecosystems and the resources they provide” (O'Neill et al., 2018) that is deliberately agnostic about specifics of causality (see Einstein on “principle theory approach” below). The comparative analysis resulting from the model's application to over 150 nation states suggests that the sociometabolic practices providing for human wellbeing (development) must be fundamentally restructured to enable basic needs to be met while leaving a much lower material footprint. This work specifically calls for two to six times greater efficiency in universally reaching thresholds for life satisfaction, healthy life expectancy, secondary education, quality of democratic institutions, social support, and income equality (O'Neill et al., 2018). In strategic terms, these statements become a call for sufficiency by recognizing that overconsumption burdens societies with both social and environmental problems as a result of a cultural focus on the pursuit of GDP growth as the key measure of progress (O'Neill et al., 2018). At present, based on the dominant development practices, societies have been given an either-or choice of meeting selected social thresholds by exceeding fairshare of environmental ceilings or failing

Fig. 1 9 (11) planetary boundaries circular visualization. From J. Lokrantz/Azote based on Steffen, W., Richardson, K., Rockström, J. et al. (2015). Planetary boundaries: Guiding human development on a changing planet. *Science* **347** (6223). 2015 Planetary Boundaries illustration.

to meet the social thresholds by staying beneath them. The SJS framework (Raworth, 2017; O'Neill et al., 2018) with doughnut-shaped visualization of people's basic needs along the inner threshold and the planetary boundaries along the outer rim conceptually locks in this unpalatable choice in treating development and destruction as a necessary strategic trade-off.

The model invites a projection of a desirable future: not exceeding boundaries and not falling short on thresholds. Regional pathways towards this goal can then be developed, incorporating specific cultural adaptations. A broad enough set of indicators will reflect the different contexts in which a given society connects with its immediate and planetary biomes. In economics, qualms about the appropriate theory of value upon which the prices of goods and services in the market should be determined (e.g., whether it is by the labor invested in them or the energy embodied in them) provide a useful conceptual parallel. Rather than settling on a single theory of value through which all worth will be reduced to a market price, we need value-articulating conceptual frameworks and associated processes by which the significance of incommensurable and quantified indicators can be deliberated and compared (Kallis, 2018). This implies that indicators should be qualitatively different, while still permitting clear quantification and boundary/threshold downscaling, and variegated to present a widely understandable model of the multidimensional characteristics of the Earth system, of which humanity is just one component.

The aforementioned analysis of the current situation in 150 nation states (O'Neill et al., 2018) indicates that no long-term balance between material and energy growth aspirations (as the physical costs of development) and infrastructural and socio-structural development attainments can be maintained using the existing conceptualization of development and the awareness of planetary constraints. The doughnut model, thus, warns that the current thermoindustrial social metabolism, predicated on a growth paradigm, cannot continue, because of the unsustainability and injustice of exceeding biophysical limits and achieving social thresholds. The majority of current states provide empirical counterexamples to Western modernity's sustainable

reproduction model of converting energy and material throughput (which are eventually bounded on a planetary scale) into social complexity (which should be fairly available to all if available to any). Those with “good enough” development attainment (achieving social foundations) excessively burden the shared planetary biome, while those who leave no burden exhibit a serious shortfall in social foundations. Any deliberate lowering of expectations of development attainment in order to causally lower its burden on the planetary biome is portrayed as a great individual and social sacrifice (Kish and Quilley, 2017), while individual nations’ partial sacrifices are seen as ineffective globally and the existing “sacrifice distribution” between nation states is seen as unjust. Moreover, historical development of indicators in the classical SJS framework (above) has been to *grow* from 0 or some minimal base to present day values, conceptually expecting the desirable future dynamic to be a simple reversal—less footprint, less development attainment.

Science today suggests that the only feasible way of keeping the average global temperature below its critical tipping point (Steffen et al., 2018) is to actively reduce energy demand and its associated material throughput in the global economy (Alfredsson et al., 2018; Grubler et al., 2018), so as to have a greater technological likelihood of successfully transitioning to renewable energy sources (Hickel, 2019). The associated throughput reduction also promises to directly reduce some of the biogeochemical pressures and transgressions upon the planetary boundaries. Economists conclude that, given available technologies for the conversion of incoming (and short-term stored) solar energy into human wellbeing, this throughput reduction will reduce aggregate economic activity, which is at present most vividly distilled in the measure of GDP. Degrowth thinkers argue that rather than directly causing the reduction of aggregate and average human development along with the additional frustration of aspirations for social wellbeing and emancipation, a planned reduction of this throughput in high-income nations will maintain an abundance of wellbeing through a fairer distribution of available resources, the expansion of public goods, and the associated deconstruction of the cultural components of the growth imperative itself (D’Alisa et al., 2014; Hickel, 2019; Kallis, 2018; Latouche, 2014). This is the conceptual underpinning of the degrowth doughnut visualization presented here.

The Degrowth Doughnut: Specifying a Safe and Just Operating Space for a Historic Conceptual and Metabolic Transformation

The mental model of a safe and just operating space for national and regional anthromic mosaics in a waste and resource constrained 21st century is a visual tool for the conceptual arrangement of an alternative approach that does not prescribe a causal-mechanical model of how to achieve their sustainability. It relies on a visionary understanding in the physical sciences that in crises of paradigms a “principle theory approach” can offer a breakout from a conceptual impasse (Einstein, 1919). This type of explanatory model does not speculate as to the detailed mechanism (think: gears, pulleys and pistons) through which observable variables are connected in the object of its study, but establishes principled and often obvious generalizations about these variables’ change constraints (think: rules, principles, flows) based on self-evident rationalizations of the experiences and axiomatic relationships in the conceptual structure. In our case this means not aggregating causal interactions between selected indicators into projections of future strategies, but constraining the overall abstract space of their possible changes. This is defined by easily understandable principles of the evolution of planetary boundaries, sustainability, democracy, or energy and materials flows. In other words, how far can biophysical changes and social structures go to stay fair and sustainable without specifying at the outset how each of them reflects upon the others. This kind of explanatory conceptualization is in line with a mounting call for solution-oriented transdisciplinary modes of rationalization for human-ecosystems interactions that can achieve global sustainability.

The degrowth doughnut recognizes that contemporary and future national anthromic mosaics’ sustainability connects their biophysical manifolds, socio-economic structures, and cultural attitudes and values in a complex interaction. It deliberately shies away from specifying the causal-mechanical connection between their elements to adhere to the principle methodology and permit a sufficient multiplicity of local and temporal variations in their dynamics. It is constrained by a principled commitment to maintaining whole anthromes within a safe and just operating space. As cautioned generally for doughnut models, “caution must be exercised in considering causative links between the different variables because interactions within and between a social foundation and environment ceiling are likely to be complex, nonlinear and difficult to confirm” (Dearing et al., 2014, p. 233).

Degrowth doughnuts lay the conceptual and analytical groundwork for a paradigm change as barometers of sustainability for policy traction and further strategic empirical studies. The visualization contains biophysical, socio-economic, and cultural segments bearing visual quantification of performance with respect to the scaled-down safe and just operating space concept—the green circular belt of the doughnut. It respects the imperative of the original doughnut (Fig. 2) to visualize necessary changes to current socio-metabolic processes through known excesses and shortfalls which must be reduced, allowing us to progressively eliminate the red bars shown leaking out of the green belt. The red bars along both the inner and outer edges of the doughnut indicate that the current complex interactions between the human population and the local or global biosphere are achieving excesses and shortfalls (quantified by the size of the red bars). It does not imply that any shortcoming in achieving the goals of the inner-ring elicits a cost upon the outer-ring, a trade-off of benefits and burdens.

Biophysically, socio-economically and culturally the degrowth doughnut visualization recognizes that states face excesses that go beyond their fair share of the planetary boundaries and societal discontent, and shortfalls in providing for a fulfilling human life and ecological stability. In the manner of scientific principle theories (Brown and Pooley, 2001) the visualization postulates which key aspects of those practices and descriptions must feature in the transition between the present and the desired future state of the system, between paradigms, quantifying these key aspects for the purpose of a comparative visual representation. For example,

Fig. 2 Doughnut model visualization for the planetary biosphere—outer boundary for ecological ceiling and inner boundary for social foundations. From Raworth, K. (2017). *Doughnut economics: Seven ways to think like a 21st-century economist*. London: Random House. Figure on p. 51: Doughnut model—planetary.

Fig. 3 Doughnut model of safe and just operating space scaled down to nation states (A) United States and (B) Sri Lanka—tradeoff between biophysical boundaries and social thresholds. Blue wedges show social performance relative to the social threshold (blue circle), whereas green wedges show resource use relative to the biophysical boundary (green circle). The blue wedges start at the centre of the plot (which represents the worst score achieved by any country), whereas the green wedges start at the outer edge of the blue circle (which represents zero resource use). From O'Neill, D. W., Fanning, A. L., Lamb, W. F., Steinberger, J. K. (2018). A good life for all within planetary boundaries. *Nature Sustainability* 1, 88-95, Figure 3: Doughnut model—National (including explanatory caption).

climate change is currently characterized by excesses in per capita carbon dioxide emissions, and by shortfalls in terrestrial forest coverage that acts as a sink for emissions. Reducing both the excesses and shortfalls would contribute to a scaled-down safe operating space. This marks a conceptual departure from the visualization of biophysical elements as only the boundaries not to be exceeded and socio-economic elements as only the thresholds to be attained. In such a conceptual structure a zero-sum trade-off is invited, and confirmed through the empirical comparison of existing national anthromes (O'Neill et al., 2018), between planetary ecological stability and human socio-economic development. Such an exclusive trade-off, with empirical support, blocks even the conceptualization of what the needs satisfaction within known planetary boundaries could look like.

Most importantly, a democracy-representing SJS supplements the biophysical and socio-economic segments with a cultural sector, thus recognizing that the attitudes and values prevalent within a given society are inextricably connected to the potential of the given anthrome's human population to adopt reproduction practices (Bhattacharya, 2017) that radically reduce the loading of the externalities of socio-economic practices onto the biosphere and that enhance known restorative properties. Metaphorically, the doughnut visualization can be likened to a human individual seeking a healthy life balance; people try to stay within the green belt of a healthy and morally fulfilling operating space through a supportive habitat and the healthy operation of the mind and body. A mental model is a diagnostic chart which can serve as a strategic departure point rather than a mechanical prescription of actions for a healthy and meaningful life explained through the details of causal interactions between diagnostic indicators. While acknowledging that this interaction exists, the doughnut chooses to remain temporarily agnostic about its details allowing room for contextual specificities within a paradigm shift in envisioning a just and sustainable state.

Understanding that excesses and shortfalls exist in all three segments of nations' reproductive practices allows us to use comparisons between different nation states (which are a mosaic of functional anthromes with some overlap) to inform their populations of the possible change strategies that operate within a fair share of the total planetary population's safe and just operating space. The implied argument is that anthromes' human populations can learn from each other and can make contributions through their actions towards overall planetary stability by developing autonomous mechanisms for reaching biophysical, socio-economic, and cultural aspirations without the unjust burdening of the planetary biosphere. The model implicitly assumes global human cooperation and mutual understanding with localized responsibility for reproduction practices. National doughnut models aim to keep the planetary load manageable and democratically accessible. A circular visualization of finite size deliberately avoids selecting some aspects as "more central," treating for example carbon dioxide emissions, human life expectancy, household debt, and mutual distrust in societies as coequally important. It also prevents a limitless addition of indicators along the ring that would result in the cognitive reaction of conceptually systematizing them into a hierarchy of causal drivers and consequences. It deliberately frames the complexity of the issue within the simple-enough constraints of a safe and just operating space that can resonate with non-experts as well.

Segments, Themes, and Indicators

Ideally, our mental models should be oriented by a set of indicators reflecting the different contexts in which human society is embedded in the anthromes. This does not mean an overburdening myriad of indicators, but a set that is qualitatively different and variegated to depict the complex multidimensional characteristics of the states' anthrome mosaics. Currently, our mental models are guided by the quasi-imposed limited set of concepts, the economic circulation modeling, which severely limits our knowledge horizon (Maria Pulselli et al., 2016). Our strategies to address the ecological and injustice crises of this century are then skewed toward greater consideration of economic output factors at the expense of physical relationship between humanity and non-human nature, and our social relationships between humans within and between communities and states. The symbiosis between the economy, environment, culture and politics must be taken into account in our mental models, strategizing for an integrated system as a whole rather than single parts in isolation from each other. As Maria Pulselli et al. (2016) have advocated that the systemic analysis unites global pressures with local actions, the mental model of the degrowth doughnut should bridge the gap between the "scientific need" for a global systemic transformation and the "governance need" for local action and policy implementation (Maria Pulselli et al., 2016, p. 228).

The principles guiding this conceptual framework include the (i) limited space with constrained properties of an absolutely finite biophysical infrastructure of the planet, (ii) emergence of properties in a "black-box" complex system, (iii) long-term consequences of the short-term transgression of tipping points, (iv) extrapolation of causes and drivers from the tracking of symptoms, (v) inclusion of life-cycle thinking into stocks and flows comparisons, (vi) history of human development as the "common intangible heritage" on a shared planet, and (vii) localized strategic action with fair share of global impact (Maria Pulselli et al., 2016, p. 231).

The degrowth doughnut mental model, as an analytical tool and a visual representation, incorporates these principles to provide a paradigm of democratically "de-growing" the energy and matter throughput of the global economic system and of re-orienting societies' metabolisms toward provisioning to meet the needs of people's well-being by distributing shared wealth through different allocation of resources and ecosystem restoration. Below the degrowth doughnut's foundation lie the shortfalls in democratic activation and wellbeing, education, health, equality, sustainable reproduction and planetary protection. Beyond its outer boundary lie the overshoots of pressure on Earth's life-supporting systems, of resource extraction, exhausting work and junk nutrition, of selfish and uncooperative popular value sets. Between these two boundaries lies the progressive but caring safe and just operating space for humanity in the 21st century metabolic and cultural transformation. The boundaries and the thresholds have broadly cultural, socio-economic and biophysical segments in which sets of indicators are grouped.

Fig. 4 Degrowth doughnut concepts used to derive the scaled-down quantified visualizations. Boundaries and thresholds exist in all three segments (biophysical, socio-economic and cultural). From Institute for Political Ecology, www.ipe.hr.

Within the cultural segment, three themes are quantified through excesses and shortfalls: planetary-minded environmentalism, democratic potential for desirable socio-metabolic change, and perception of human wellbeing. The indicators track popular attitudes whose overshoots and shortfalls in a nation support a reluctance to engage in democratic activation for reducing the human impact upon local and global biospheres. They also quantify excessive frustration and apathy obstructing design and implementation of the novel social reproduction mechanisms necessary for metabolic change, as well as shortfalls in positive support for degrowth-oriented policies (van den Bergh et al., 2019). It is important for an integrated mental model to keep track of the existing and future life-satisfaction through average self-reported wellbeing (health and satisfaction). Perceptions, though subjective, are important to track as they are the final outcome of the democratically supported metabolic practices among rational reflective members of the human community. They logically connect to the socio-economic segment of the model, to its theme of democratic infrastructure (Fig. 4).

Four themes are included within the socio-economic segment: health, democratic infrastructure, material security of individuals, and material and energy flows of the whole society. Indicators in the theme of material security deliberately do not include a measure of average personal or national income, a cornerstone of current economic tracking of social metabolism which motivates further commodification of public wealth. Current metabolic practices expose citizens to overwork and debt, motivating the externalization of the associated costs by imposing them upon the rest of society and the biosphere (Rosnick and Weisbrot, 2007) while historic attainments in productivity and automation allow for less time to be spent on paid work and for more time to be dedicated to other forms of care and restoration. Conceptually the closest concept to the biophysical segment of indicators is the theme of energy and materials use (Fig. 4), including indicators of per capita energy use, national material footprint and share of renewables within final energy consumption.

The biophysical segment of the doughnut conceptually joins the original circle of planetary boundaries (Fig. 1) with the desirable thresholds of climate change stabilization and ecosystem restoration. It carries with it the themes of human food production (agriculture), biodiversity protection, and climate change (Fig. 4). These are the three crucial biophysical themes for every anthropocene to consider in this century.

Safe and Just Operating Space in Biophysical, Socio-Economic and Cultural Quantification

On the overall doughnut we therefore find external rim boundaries in climate change drivers, pollution, extraction, energy and materials flows, work and debt burdens, inequalities, poor nutrition, the perceived failures of democratic institutions and social cohesion, as well as popular opposition towards action for the preservation of planetary ecological stability. Like the planetary overloading of ecosystems with pollutants and of the atmosphere with climate change-driving greenhouse gases (Fig. 1; Rockström et al.,

Fig. 5 Degrowth doughnut visualization with 33 indicators for a realistic small European state. *Cultural*: CP, corruption perception; JD, job dissatisfaction; FWD, frustration with democracy in country; D, distrust; A, anthropocentrism; CI, climate change indifference; HP, health perception; FP, flourishing perception; DS, degrowth support; GE, global environmentalism; RP, renewable energy prioritizing. *Socio-economic*: EU, energy use; MU, material use; O, overwork; DIR, debt income ratio; GI, gender inequality; FF, fatty food; RE, renewable energy %; SE, social equality; E, education; VT, voter turnout; H, healthy life expectancy. *Biophysical*: LUC, land use change; C, CO₂; BN, biodiversity neglect; NU, nitrogen use; PU, phosphorus use; FU, freshwater use; FA, forested area; CFR, climate change flood resilience; PW, protected wilderness area; SQ, soil quality; OF, organic farming area. From Institute for Political Ecology, www.ipe.hr.

2009), all these cultural, socio-economic and biophysical factors present excessive burdens on states' fair share of the transformational 21st century social metabolism. They simultaneously hasten the push towards ecosystems collapse and disable societies' cooperation to avert it. Crossing these boundaries moves the states out of a safe and just operating space.

The inner rim lists thresholds for ecosystem restoration, sustainable food and energy provision, social equity, democratic participation, human health, wellbeing, and pro-environmental activation. Shortfalls in reaching these thresholds, like the shortfalls in reaching the goals of development in nature-society doughnut visualizations (Fig. 2), signal insufficiencies in the existing conversion of work and resources into human flourishing and ecosystem stability. The degrowth doughnut's inner ring—its restorative foundation—sets out the basics of 21st century just and sustainable life on which no society should be reneging. The red bars quantify shortfalls within the present organization of an ever-increasing throughput driven by fossil fuels, indicators of what a democratic and just operating space for the climate and extinction constrained 21st century anthromes must strengthen and preserve.

Upon facing the doughnut's themes and indicators, the rationally trained mind gropes for causal mechanisms to be extracted out of the structure: what are the greatest "bads" driving the greatest "goods" and what causal interactions exist between them. Here it is worth bearing in mind Einstein's injunction against premature constructive theory developments (Howard, 2017). Such urges, though understandable, lie in the eye of the reader and are intended by the structure of the doughnut. There is a myriad of logical and empirical connections between the different themes placed around the ring of the doughnut, as well as between the different indicators chosen to quantify them through a globally comparative array. A future sustainability science paradigm should, indeed, determine what these connections are (in particular if there are any feedback loops which drive nonlinear behavior), and seek to discover a fair and effective way to influence their evolutionary dynamics. As a principle theory tool, the doughnut offers a blueprint to transcend the trade-off between development and devastation, to transcend the conceptual paralysis resulting from a lack of mechanism connecting planetary sustainability with the 20th century development. Democratically addressing climate change and biodiversity loss, while providing for people's wellbeing, decent health, nutrition, and material security through a fair and sustainable volume of material and energy flows will all be a part of the safe and just operating space for a redesigned societal reproduction in the 21st century.

In that sense the themes are conceptually more important than the indicators chosen, though the latter must have a realistically broad coverage of different nations or a link to suitably interchangeable proxies to allow for broad enough comparison and

longitudinal temporal tracking from readily available databases. Moreover, while the available comprehensive global statistics are collected on the national scale, most of the themes are open to scaling down to the level of specific metabolically integrated areas rather than politically delineated anthrome mosaics. Likewise, due to changes in energy production and global metabolic flows in the future some indicators could lose significance or sensibility. But an adherence to the principle of seeking a safe and just operating space by scaling down, in a fair way, from known global limits and potentials through concepts of climate stabilization, wellbeing, care for the planet, and fair distribution of its resources, will yield comparable doughnut visualizations.

The usual objection to the quantification of variables within highly complex interactions beyond a simple causal-mechanical model is that it is the quality and not the quantity of the characteristics and phenomena associated with the variables that is really important. This becomes especially pertinent when transdisciplinary assessments, like the doughnut, combine well-known quantitative indicators like carbon and nitrogen pollution with less familiar ones like neglect of biodiversity protection, healthy life expectancy of human population, debt to income ratio of households, or average level of satisfaction of survey respondents with their current job. In the first instance the quality versus quantity objection applies to all indicators, and is usually already addressed within the entrenched scientific disciplines where these indicators are most often used. Indicators do indeed provide descriptions, explanations, and predictions within the standard conceptual frameworks of those disciplines. Their broader discursive acceptance then stems from the popular visibility of respective disciplinary narratives. For example, even the most readily used national carbon emissions data in popular presentation are actually opaque to the debate about short-cycle carbon emissions, the debate about necessary and luxury emissions, and the debate about emissions created outside the specific territory through trade and intercontinental transport.

In the second instance, the quality versus quantity objection renders the transformative role that the principle theory approaches play within scientific paradigms impossible. The tracking of categorical differences in orders of magnitude and coarse-grained trends are the conceptual instruments for reasoning about the possible and impossible changes under constraining principles. This is what allows for workable explanations across a range of otherwise confusing and seemingly disparate phenomena, with a temporary suspension of attention to fine qualitative differences between their constituent elements. A degrowth doughnut is a visual model motivated by the call for a redesign of socio-metabolic interactions to avoid the worst exemplars of environmental degradation and the breakdown of complex modern societies; it is not the fixed mechanism of the causal links between drivers of environmental change and (for example) subjective experiences of poverty.

The consequential objection refers to a strategic action based on the assessments presented in national doughnut visualizations, namely that it is possible to implement courses of action that will reduce the named excesses and shortfalls within the doughnut without seriously improving the quality of life and sustainability of societies and the ecosystems they are in interaction with. In other words, a sort of malicious defeatist short-circuiting of the doughnut themes and indicators without effecting a serious change. This amounts to the objection that the themes and indicators are not well chosen, do not push the right buttons, or even that such indicators cannot be chosen at all because the problem is unfathomable. While short-circuiting is, indeed, a logical possibility, the diverse and widespread nature of the indicators is designed to spot this practice precisely by not fetishizing the crucial few and by maintaining agnosticism about the causal chains between them.

While the questions and samples in the surveys might be engineered to register lower levels of distrust and anthropocentrism, along with higher levels of environmentalism, social equality, and voter participation, a simultaneous action to manipulate the social survey results on a global scale together with reduction in soil erosion of agricultural land and reduction of fresh water and energy use will take at least as much coordinated intellectual and social effort as genuinely attempting to transition to an alternative modernity that will be sustainable by doughnut measures. This answers the final question of the use of the doughnut for anthromes that have no excesses or shortfalls to begin with, or that are capable of removing excesses and shortfalls relatively soon. Such societies and the biomes they inhabit are best positioned to redesign notions of progress and sustainability for the planet; in other words, doughnuts are not designed to be eternal ideological crutches, and the sooner they become uninformative and obsolete because of an end to the practices which fall outside of the safe and just operating space for humanity, the better.

Application of the Model

The doughnut representation with its quantified boundaries and thresholds reminds us that boundary transgressions related to biophysical processes, social justice, and societal commitments to sustainability are already occurring. Shortfalls also already exist in terms of ecosystem restoration, democratic governance, carbon neutral energy provision, and popular support for socio-metabolic transformations that contribute a fair share towards global sustainability. Continuing along the same path by focusing on economic growth as the foundation for an industrial socio-metabolic mechanism to process resources into wellbeing is now creating more problems than it solves. Growth is a maladaptive strategy towards achieving a just sustainability in this century (D'Alisa and Kallis, 2016).

The example doughnut for a peripheral European state in [Fig. 5](#) (based on publicly available data) presents no shortfalls in the average popular perception of personal mental and physical wellbeing (HP, FP) or in the prevalence of values compatible with orientation to new metabolic regimes and globally environmentally beneficial practices (DS, GE, RP). This is the state's cultural potential on which to build transformative strategies. It is, however, hindered by a slight majority of anthropocentrism and a predominantly negative perception of society's current democratic potential and social cohesion (FWD, D).

Building institutions through which collective action on degrowth transition can be fostered to turn its cultural potential into action, together with increasing voter turnout (a shortfall in the socio-economic segment) to enhance representativeness of the existing and new democratic institutions, could lead to desirable outcomes. Mild job dissatisfaction (JD) and overwork (O) present a call for a different organization of work for the economic provision of necessities and wellbeing. At the same time, shortfalls in social equality (SE) and excesses in household debt (DIR) speak to potential instruments for the redistribution of social surplus in the eventual redesign of economy or for public instruction as to the existing burdens of current economic practices.

Gender inequality (GI) must be further reduced to strengthen democratic governance potential, while mean expected educational attainment (E) for contemporary youths is yet another positive area on which there is potential to build. Energy and material flows (in terms of their effect on the planetary boundaries) are already comparatively low and should be maintained, building on the public support for renewable energy provision (RP), which currently exhibits a great shortfall from the perspective of the necessary decarbonization (RE). Carbon emissions and land use change as drivers of climate change need to fall back within the safe operating space, but forest coverage is already optimal. Immediate action is needed in the area of flood protection (CFR) to prepare for increased precipitation already locked-in under climate change. While neglect of biodiversity protection is not excessive, more areas need to be set aside for natural habitats with minimized human impact. Feeding the population with local quality nutrition is a priority, not just because of the excessive loading of the biosphere with artificial fertilizers, but because of the excessive content of lipids in the national diet, poor soil quality, and insufficient organic farming areas (which also carry biodiversity benefits).

Overall, this is a national territory, a political unit governing several anthromes whose primary tasks are securing healthy local nutrition for its population and strengthening its democratic infrastructure for a communal and democratic determination of context-specific sustainability goals. It already has the technological instruments for sufficient social reproduction, which must shift towards renewable energy. Agriculture and renewable energy transformations will help to reduce its contribution to the loading of the planetary biosphere with pollutants, which is something its population is supportive of but also impotent in acting upon because of frustration with the existing democratic infrastructure. Meanwhile, poverty, unsatisfactory work, and debt burden make the existing model of social surplus distribution unsatisfactory despite the fact that its volume (almost) avoids exceeding its fair share of planetary safe operating space. In comparison to other national anthromes with greater biophysical and socio-economic boundary transgressions and existing cultural shortfalls, this state has a more institutional and less material infrastructural change to make.

The doughnut model presents a visual tool for quantifying deviations of social reproduction of the politically determined anthromic mosaics from the safe and just operating space bounded by biophysical, socioeconomic and cultural downscaled indicator values. The doughnut ring contains outer boundaries in climate change drivers, chemical pollution, extraction of renewable limited resources, energy and materials flow, work, debt, gender inequality, overload of insufficient nutrition, residents' perception of democratic institutional failures, social disintegration, and popular opposition towards acting on the preservation of planetary ecological stability—current possible excesses of social metabolism and dominant culture. Its inner boundaries consist of ecosystem restoration, sustainable food and energy production, equality, democratic participation, health, popular perception of personal wellbeing, and pro-environmental values—current possible shortfalls. The model provides a base for guiding strategies of urgent and radical socio-metabolic transformation that human politics must put in practice to achieve a just global sustainability.

Abstract

Degrowth is a social movement and a research framework which advocates for a transition to sustainable and just forms of social organization. It proposes to achieve this double objective by “de-growing” the energy and matter throughput of the global economic system and reorienting economic activity away from production of material goods toward provisioning to meet the needs of people’s well-being by distributing shared wealth using different ways of allocating resources (Kallis, 2018). As a “transitional discourse” envisioning alternative societies built on “ecological integrity and social justice” (Escobar, 2015, p. 1), it approaches the transition from a systems-thinking perspective that combines the values of ecology, justice, well-being and democracy (Demaria et al., 2013) with the theoretical foundations of ecological economics, political ecology, post-development, environmentalism of the poor and limits to growth. The proposals in academic literature cluster on (1) reduction of the environmental impact of human activities, (2) redistribution of income and wealth within and between countries, and (3) transition from a materialistic to a convivial and participatory society (Cosme et al., 2017).

Introducing Degrowth

Degrowth emerged as an international movement in the early 2000s from a dissatisfaction with the official responses to climate change and planetary environmental degradation, whose foundations were laid out in the Brundtland Report (1987) and the UN Framework Convention on Climate Change (1992). These documents have explicitly wed the climate action of governments to their commitment to free trade and economic growth, although these two pillars of the capitalist system of production have, since the onset of the industrial revolution and particularly since the Great Acceleration after WWII (Steffen et al., 2011), necessitated a growing appropriation and degradation of planetary ecosystems. The contemporary degrowth movement has three aspects, theoretical, activist and political, which are not rigidly integrated into a common framework but there is a continuous interaction between actors and ideas, especially in the international degrowth conferences (Martínez-Alier et al., 2010). Unlike the ideals of sustainable development, green growth, and green capitalism, degrowth insists that environmental stability and sustainability can only be achieved through a departure from the present growth-oriented global capitalist system.

The term draws its inspiration from *The Limits to Growth* report to the Club of Rome published in 1971 and was coined a year later in French as “décroissance” by French-German philosopher of political ecology André Gorz, only to be confirmed a couple of years later in the translation of a work by Romanian-American economist Nicholas Georgescu-Roegen, the founding figure of ecological economics. The word “officially” entered into English with the first Degrowth Conference held in Paris in 2008 (Demaria et al., 2013, p. 195). Initially the idea of “décroissance” rallied together the grass-roots activists working on issues such as environmental justice, protection of the environment, opposition to extractivism, and infrastructural and energy projects alongside the practitioners of alternative forms of organization of social production and consumption like permaculture, cooperatives, ethical banks, cohousing, squatting, and recycling, gradually consolidating into an international social movement (Demaria et al., 2013, pp. 202–203). Regular international conferences crystallized it also as an activist-led research agenda (Martínez-Alier et al., 2011) and a platform for political advocacy. The research agenda received its provisional manifesto in *Degrowth: A Vocabulary for a New Era* published in 2014, whereas the political advocacy had its first high-profile international foray with the Post-Growth Conference held at the European Parliament in 2018.

The foundational insight of degrowth is that there cannot be endless growth on a finite planet. While the Earth is not an entirely closed-off system, almost no matter enters the atmosphere, and the incoming solar energy is not readily convertible into work that is able to satisfy human needs. Thus, the regeneration of energy stocks and the recycling of matter available for human use can unfold only at a very slow rate. However, the pattern of continuous economic growth inaugurated by capitalism is based on disregard for the overall limits of planetary stocks and flows, counting on substitution of the depleted sources with hitherto untapped ones and simultaneous displacement of ecological impacts to global economic peripheries. Over the last century, global material extraction and primary energy consumption have grown roughly tenfold to 70 Gt/year (Schaffartzik et al., 2014) and 525 EJ/year (Smil, 2016, p. 241) respectively. The world’s ecological footprint currently exceeds the annual bioregenerative capacity of the planet by 70%

(Global Footprint Network, 2013). Human use has significantly altered 75% of global ice-free land (Ellis and Ramankutty, 2008) and 66% of marine environments (IPBES, 2019), and appropriates around one-third of the net primary production of terrestrial systems (Haberl et al., 2014).

This expanding dynamic of extraction has led to a number of negative impacts on Earth's biophysical systems resulting in dangerous climate change, biodiversity loss, acidification of oceans, soil degradation, and land-use change, pushing the planetary systems beyond the limited variability that has provided a safe operating space for human societies to thrive over the last 10,000 years of the Holocene (Rockström et al., 2009). The effects of these disruptions are distributed unequally, hitting both the most economically (Diffenbaugh and Burke, 2019) and environmentally disadvantaged populations and countries the hardest. At present, no country stays within its "fairly apportioned global biophysical boundaries" while also meeting the basic needs of its people (O'Neill et al., 2018). From a degrowth viewpoint, in order to bring societies within the planetary boundaries, the pattern of expanding extraction has to be reversed, and the provisioning systems addressing societal needs must be organized differently.

The patterns of resource-use change throughout history, along with the modes of production and forms of allocation. These patterns define socio-metabolic regimes (Fischer-Kowalski, 2011). The dominant socio-metabolic regime in the contemporary world is defined by a system of industrial production enabled by the high energy intensity of fossil fuels and global free trade. This system is organized around the capitalist separation of workers from the means of subsistence. This separation forces them to work for a wage in order to be able to secure their subsistence by purchasing commodified goods and services in the market, and to work beyond the level that meets their needs in order to generate a surplus. The surplus produced by the workers is appropriated by the owners of capital for private consumption and, fundamental to sustaining the dynamic of growth, for reinvestment into further accumulation of capital. This process of capital accumulation under the conditions of competition is accompanied by an imperative to raise productivity, resulting in growing economic output, i.e., an ever-greater quantity of goods or services produced in a given period of time. This growing economy has a strong historical correlation with the growth of material footprint and CO₂ emissions (1% increase in GDP resulting in 0.6% increase of material footprint (Wiedmann et al., 2015) and 0.5–0.8 increase in emissions (Burke et al., 2015)).

Economic growth at the national level is measured by an increase in the Gross Domestic Product (GDP). Economic policies are drawn up to keep the GDP growing year after year, and GDP growth is a key performance indicator upon which governments stand or fall. The healthy annual growth rate of an advanced economy is considered to be between 2% and 3%, leading to a doubling of economic activity roughly every 24–35 years. The drivers behind this expectation of growth are twofold. On the side of system reproduction, capital is borrowed with the expectation that future growth should repay the debt and interest that will, in the next step, serve as capital for future borrowing. On the side of system justification, the competitive forces of the market tend to reduce wages and create inequalities, whereas growth allows policymakers to promise an increase in wages in the future without needing to redistribute the existing social wealth in the present.

However, researchers on the subject of inequality (Hickel, 2018; Milanović, 2016; Piketty, 2014) have documented that in advanced economies the expected trickle-down effect of wealth has not happened since the 1970s: as wealth has become concentrated at the top, wages have stagnated. Even with the exceptional effect that reduction of absolute poverty in China has had on global poverty, relative poverty in the world has increased since the 1980s (Chen and Ravallion, 2012). Alternative indicators of social progress like the Genuine Progress Indicator (Anielski and Soskione, 2002) reveal that once the negative social and environmental impacts are accounted for, beyond a certain level growth does not bring an increase in objective and subjective well-being and is environmentally disastrous (Kallis, 2018, ch. 4).

While there are hopes that growth can be maintained by making economic processes green and sustainable, empirically there is no evidence that economic growth can be achieved with simultaneous reduction of greenhouse gas emissions (GHG) and material extraction for a sustainably long-term period on a global level (Hickel and Kallis, 2019). This suggests that if the assessment of the Intergovernmental Panel for Climate Change (IPCC, 2018a) warning against runaway climate change, and the assessment of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES, 2019) warning against the unprecedented decline of biosystems, are to be taken seriously, human action faces a difficult choice between rapid reduction in throughput or the potential collapse of ecosystems. Without the assumption of near-complete and widespread substitutability of ecosystem services with anthropogenic goods and services, ecosystem collapse would also mean a subsequent economic collapse. Facing this choice, degrowth offers diagnoses and strategies (Demaria et al., 2013, p. 194) that address the major social obstacle to the transformation that is needed in order to make the global social metabolism sustainable: how to prevent that the rapid reduction in throughput does not lead to a widespread and forced reduction in social well-being.

Degrowth Economics: Bringing the Economy Back Into the Biosphere

Degrowth is, in principle, agnostic as to whether the planned reduction of throughput will lead to a reduction in economic output. The goal is not economic depression, but long-term sustainability and societal well-being. However, long-term sustainability might not be feasible without an economic slowdown. The reduction in GHG emissions needed to stay within the Paris Agreement limit of a 1.5 °C or 2 °C increase in average global surface temperature by 2100 compared to pre-industrial levels is achievable only if the world economy rapidly abandons its present pattern of growth driving the expanding use of cheap and polluting sources of energy. The current "business-as-usual" approach with unchecked growth and without rapid and planned decarbonization puts the Earth on a likely pathway of an increase of 4 °C or more. The world would have to cut net emissions to zero by 2050 in order to stay under

1.5 °C or by 2070 to stay under 2 °C (IPCC, 2018b). The necessary annual reductions in GHG emissions to achieve those targets at a zero-growth rate would be 6.8% and 4% respectively, but at a 2% growth rate they would have to be as high as 8.8% and 6% respectively (Hickel and Kallis, 2019, p. 15).

This is, however, far above the most optimistic predictions, which put GHG emissions reductions at a maximum 4% annually—implying that a reduction for a 2 °C increase might be achievable, but only with the rapid deployment of deep decarbonization strategies (transition to 100% renewables, afforestation and soil regeneration, and shift to alternative production processes) and, crucially, a zero-growth rate (Hickel and Kallis, 2019, p. 15). This scenario may still be impossible to implement, requiring the deployment of negative emissions technologies (Gasser et al., 2015). Most prominent among those is bioenergy generation with carbon capture and storage (BeCCS): the combination of planting crops for energy generation and capturing released carbon dioxide in order to store it underground. This combination of technologies is far from maturity, far from the scale of carbon capture needed, in competition for land with agriculture and biodiversity, and risks, in the case of seismic instability, massive carbon leakages from the underground storages (Anderson and Bows, 2011).

The economics of growth is thus at odds with the biophysical realities of climate change mitigation. It is for this reason that degrowth has taken up the task of challenging the economic orthodoxy which underpins climate change policies. However, this undertaking necessitates that degrowth mounts a critique not only of growth but also of the economic science for which it is axiomatic. Namely, the economic models used in the Intergovernmental Panel on Climate Change (IPCC) integrated assessment scenarios that assume, without exception, continued economic growth. These models are built upon the assumption of market equilibrium and are deterministic in a way that cannot account for uncertainties inherent to disequilibrium processes such as climate change, which can trigger unforeseeable changes in social systems over long periods of time, or in the case of the IPCC scenarios until the end of the 21st century (Spangenberg and Polotzek, 2019, p. 199).

Furthermore, they consider growth in GDP as the optimal outcome of decarbonization scenarios, while scenarios leading to a reduction in GDP are considered negative, displaying a bias against substantial changes in societal patterns of production and consumption (Spangenberg and Polotzek, 2019, p. 199). The reason why all economic models assume that growth will occur is that the fields of economics and economic policy are dominated by formal approaches which analyze economic processes in terms of market pricing, exchange values, and money, disregarding substantive determinants of economic processes like the metabolic interactions between society and the environment, politico-institutional structures, and the societal purposes of economic processes (Gerber and Scheidel, 2018).

The dis-embedding of the formal economy from its biophysical, socio-metabolic, and political determinants began historically with the emerging economic science in the 18th century striving to differentiate itself from the political economy and economic history that had dominated its early development. Until the 18th century, economics was no more than a practical art of managing the limited resources of land, estates, and populations. With the work of moral philosophers Adam Smith, David Ricardo, and John Stuart Mill, the definition of political economy gradually shifted away from concerns as to the purposes which guide economic activity to this activity's underlying laws (Raworth, 2017, ch. 1). With the marginalist revolution of the late 19th century, the discipline completed its boundary-work (Gieryn, 1983), succeeding in differentiating itself from neighboring disciplines through the demarcation of its distinct object of inquiry in the form of markets and its methods of formalization in the form of price theory (Gerber and Scheidel, 2018). As the capitalist mode of production emerged and spread across Europe, the focus of economic science shifted from the management of resources to the improvement of productivity, markets, and trade. The consolidation of economics thus proceeded apace with the consolidation of capitalism and the modern state.

The economy as the object of political and institutional governance assumed its present contours in the 1930s and 1940s in response to the Great Depression, ending the period of laissez-faire capitalism. The leading economic nations start to reconceive the national economy as a dynamic system of interactions between economic actors, whose value can be estimated by national accounting, measured by the gross national product and directed by policies which are primarily the responsibility of economic experts who are institutionally safeguarded from direct democratic challenges (Mitchell, 2014). The greater institutional regulation of free markets by national governments accomplished in capitalist economies after WWII then underwent a gradual erosion as international free trade began to intensify, leading to a period of neoliberal globalization during which the global integration of free markets severely limited the capacity of government to plan and direct economic processes and to limit their social and environmental impacts.

During the historical development of economics, substantive concerns of human livelihood and interaction with the environment got pushed into the background. The economy was reconceptualized, as illustrated by the famous circular flow diagram drawn by Samuelson (1948, p. 264), as an isolated system where exchange values circulate between households and firms and no resources are taken from nor waste released into the environment (Daly, 2019, p. 10; Raworth, 2017, Introduction). This is a reductive and distorted image that ecological economics has taken up the task of setting straight. In his foundational contribution to ecological economics *The Entropy Law and the Economic Process* (1971), Nicholas Georgescu-Roegen posited that all economic activity is constrained by thermodynamically irreversible increase of entropy: it takes matter and energy from nature in a condition of higher order and availability for transformations—and returns waste and dissipated heat into nature in a condition of higher disorder and reduced availability. The process of degradation is a necessary byproduct of all value creation, it is irreversible, and recycling can only be achieved with a substantive investment of energy resulting in further degradation.

Georgescu-Roegen thus placed the economic system back inside the biosphere. All value produced in an economy crucially depends on nature's sources of matter and energy, and sinks absorbing waste and dissipated heat. In fact, humans, by drawing on water, food, matter and energy from environments locally and globally, depend for their metabolic reproduction on exosomatic

services of nature—maintenance of biological and social structures that compensate for the inevitable losses due to entropy (Ayres and Kneese, 1969). The basic human endosomatic metabolic rate has been expanded in hunter and gatherer societies through the exosomatic appropriation of food and heat from firewood by a factor of three to four to around 11 GJ/capita annually, in agricultural societies through plant cultivation and animal husbandry to 20–80 GJ/capita, and in industrial societies primarily through fossil fuel burning to 280 GJ/capita (Fischer-Kowalski et al., 2014, pp. 21–22). These expanding patterns of appropriation, alongside increasing complexity and necessary reflexivity of the symbolic or social realm (Ostrom, 2009), have characterized the evolving social metabolism of human societies.

The following energy-materials-culture nexus defines the social metabolism of contemporary growth-oriented capitalist societies. The energy-intensive stocks of fossil fuels are used for energy conversions that increase the productivity of human labor in the transformation of growing quantities of matter into products. Products thus embody the matter and energy that went into producing them. Products sold as commodities can be machines destined to be used in a future production process, or goods and services destined to be irreversibly expended in the consumption process needed for continuous social reproduction (Bhattacharya, 2017). Overall, a section of the human population, the class of capitalists that owns the means of production, employs workers but pays them less than the value of the product of their labor, appropriating the surplus that is left once the wages, machinery, raw materials, energy, and other operating costs have been paid. The greater the ratio of appropriated surplus value to wages, the greater the rate of exploitation of labor. Exploitation happens as an intrinsic and systemic feature of the capitalist organization of social production and indirectly reproduction, as capitalist class must keep drawing as much surplus labor as possible due to systemic commitment to market competition. But capitalists are also able to dictate how the social surplus will be produced and to what ends it will be expended, and thus as a class have more economic power in defining the purposes and priorities of the societal process of production and society's continuous reproduction over time.

Market competition between capitalist enterprises creates a structural imperative that a large part of the surplus must be reinvested into even more productive uses by mobilizing more human labor, more socially reproductive labor that goes into sustaining laboring humans, more resources from nature, more cheap and hard labor from poorer economies to extract those resources, and more knowledge and machines that make that labor more productive. This ultimately leads to the creation of even more surplus, thus engendering a pattern of self-perpetuating growth. However, that growing investment toward productive use also requires growing expenditures on nonproductive consumption in order to absorb the growing amount of product, resulting in an unstable spiral of overaccumulation and underconsumption that unleashes capitalist crises (Kallis, 2018, ch. 2). These are in turn used to reinforce the political imperative of a return to growth, or the current economic system would collapse. The expanding appropriation of resources from nature is thus coextensive with successfully pursuing the imperative of growth, increasing environmental impact through an expansion of social metabolism and socio-economic insecurity through a spur for greater overall exploitation.

Degrowth's critique of the economics of growth—and of the broader dominant “culture of growth” (Latouche, 2009), “growthism” (Daly, 2019) and the “growth paradigm” (Kallis, 2018)—builds upon the insight that, ultimately, the decoupling of the economic system from the throughput of matter and energy is impossible (Parrique et al., 2019). The assumption that all social and environmental challenges can eventually be overcome by maintaining continuous growth ignores the fact that economic processes will always have environmental costs, which on a finite planet only get displaced from one ecosystem to another as the global system of production expands from location to location and replaces one technological process with another. Historical evidence at the global level shows that environmental impacts cannot be substantively diminished in a sustainable way while maintaining economic growth in its present form. Starting from there, degrowth economics pursues the following objectives:

- to reembed the economy into society, and the society into Earth's systems (Raworth, 2017),
- to reconceptualize the economy as “the instituted process of interactions between humans and their environments, involving the use of material means for the satisfaction of human values” (Kallis, 2018, ch. 2),
- to develop policy proposals for the reorganization of the economy and the attendant political system to bring the socio-metabolic processes within the biophysical boundaries,
- to analyze how the growth-oriented capitalist system produces artificial scarcity as coercion to wage labor (Hickel, 2019) and how it “solves” this scarcity through the massive overproduction of material things,
- to analyze how the growth-oriented capitalist system creates dynamics of power, social hierarchies, and oppression through the private appropriation of social surplus (Kallis, 2018, ch. 2), and
- to develop a social system of distribution that would lead to an economy of abundance and human well-being based on sharing.

Degrowth as a New Political Imaginary

Degrowth takes a nonreductivist approach to societal transformation. The transformation that it advocates starts from the understanding that the existing social reality is shaped by an economic system that locks the majority of the world's population into patterns of production and consumption based upon a premise of economic growth and growing throughput. However, as the economic system has coevolved with the political system from which it arose, this lock-in is predicated upon a geopolitical order that is founded on, and legitimizes the subjugation and exploitation of social groups as well as the destruction of nonhuman nature. Therefore, the societal transformation that degrowth advocates requires a reimagining of the political—a repoliticization of

fundamental social questions and antagonisms regarding a common trajectory and alternative visions of the future (D'Alisa et al., 2014a). To maintain the cultural complexity of contemporary life with a biophysically less impactful metabolism, a degrowth transition needs concrete proposals on how each of the processes that maintain high throughput (energy supply, technological infrastructure, financial system, agriculture, manufacture, etc.) could evolve in the desired direction. This is the nonreductivist aspect of degrowth: positing that the future transition has to be conceived of and developed multidimensionally within the boundaries of the Earth's biophysical systems and flourishing cultural emancipation (cf. *Mental Models of Sustainability: The Degrowth Doughnut Model*, this volume).

Degrowth acts as both a provocation and an opening for a new political imaginary, coming amid the burgeoning realization that the imaginary of endless growth on a finite planet can no longer be sustained. The disavowed environmental impacts of the endless growth have become so severe that they are pushing Earth's biophysical systems beyond their limited Holocene variability, presenting a grave threat to the safety and survival of a growing part of the world's population. Therefore, degrowth insists on an unpopular yet realist position that there is no empirical evidence to believe that throughput can be lowered globally and for the foreseeable future without "de-growing" economic output (Hickel and Kallis, 2019). However, acknowledging that the lowering of economic output might adversely affect the well-being of many and particularly of those who are disadvantaged in unequal societies, and acknowledging that people equally fear the loss of socio-economic security as they fear the impacts of the climate crisis (Clayton et al., 2017), degrowth proposes that societies produce less material output while socializing care for the well-being of all. Such an ideal runs counter to the hegemonic common sense that the imaginary of growth instills in governments, experts, and general populations.

After the end of socialism in the countries of Eastern Europe, a social system that prioritized equality but not sustainability as it followed the productivist, extractivist, and growth-oriented trajectory of industrial development, there seemed for decades to be no alternative imaginary of what could supplant the present capitalist social system that prioritizes neither equality nor sustainability. This is where degrowth steps in. It is developing grass-root alternatives and proposals (see the next section) that are both concrete to the extent that they are workable in practice and utopian to the extent that they cannot be aligned with a growth-oriented capitalist society. These real utopias guided by the principles of equality, democracy, and sustainability (Wright, 2013) propose prefigurative practices that show how to organize anything from social production, care provision, financial system, technology, transport, and transit to the collective and convivial expenditure of social surplus on human self-realization. By inserting these practices into the social reality, degrowth practitioners foster new common senses (D'Alisa and Kallis, 2016) rooted in the material organization of the everyday which respond to the looming ecological crisis and demonstrates, practically, that growth is not necessary for human well-being.

These practices are plural and frequently heterogeneous, as they reflect the plural concerns and heterogeneous conditions that exist within and between capitalist societies. They are not axiomatic deductions from a program of transition, because degrowth does not envision transition as the top-down implementation of a societal model, but as an evolutionary process of change which can build momentum, spread, and become generalized at various social scales and across societies as the present capitalist social formation fails to respond to nonlinear disruptions to the environment and to deepening social disparities. However, in this heterogeneity, such practices are the building blocks of a degrowth transition, and share a set of values and orientations beyond the fundamental assumption that they work toward lowering throughput and increasing collective well-being:

First, they require both the dissolution of the capitalist class division which features private appropriation of surplus and the suspension of capital accumulation (Blauwhof, 2012; Kallis, 2018, ch. 6), because the appropriation of surplus gives the power to direct social development while capital accumulation drives the process of economic growth.

Second, they emphasize collective forms of ownership and management of resources like public goods and commons, where the perspective of utility is commensurate with the collective good and its planetarily defined limits. Commoning—practices of creating sustainable systems of provision and peer governance that produce shareable goods as opposed to private accumulation or autocratic allocation (Bollier and Helfrich, 2019)—social and natural resources would shift the emphasis toward sharing and creating collective abundance through the careful maintenance of those resources.

Third, they are guided by environmental justice concerns, starting with the understanding that affluent societies have benefitted from the processes of conquest, imperialism, and "unequal exchange" (Hornborg, 2014; Moore, 2015), and that their economies continue to disproportionately benefit from the historical and present GHG emissions, material extraction, and appropriation of primary production of ecosystems, which have and continue to undermine the ecological and social integrity of less affluent societies. Degrowth thus demands a radical reduction in resource consumption primarily by affluent societies. However, it also acknowledges that not all of the world's population can converge upon the resource-hungry organization of life in affluent societies, as that would require bioregenerative capacities several times greater than what Earth can offer, and collectively following the model of Western development would be detrimental to all. Development has wrought devastation across the Global South and, as a result, these societies ought to be given the opportunity to pursue their own distinct paths of social development based on vernacular forms of sustainable economic organization. However, one precondition is that the Global North first abandons the growth-oriented development which forces those societies to integrate themselves into the capitalist world economy, entering with them into an alliance of de-development (Latouche, 2009, pp. 57–58). This would result in a pluriverse—a different way of understanding existence that permits countless groups of people to create their own distinctive but overlapping cultural realities, a recognition of multiple ways of being in the world.

Fourth, use values in capitalist economies are made commensurate and exchangeable through commodification and prices. This dis-embeds social needs from their social and environmental conditions and places them under the dynamic of self-sustaining

accumulation with a general disregard for any social or environmental damages. Yet the value of needs and damages cannot be made commensurate without the dynamics of economic power working behind the backs of social actors, and are thus, in principle, incommensurable (Martinez-Alier, 1990). In a degrowth society, there would be a reembedding of values within their social and environmental contexts and an institutional and democratic mediation of production and exchange (Polanyi, 2001 (1944)).

Fifth, as degrowth implies a reorientation from the production of commodities to the provision of relational goods, the focus of a degrowth economy would be on care-work, which tends to disproportionately fall upon women and migrants, in turn requiring a fundamental reorganization of social roles along the principles of gender and racial equality (D'Alisa et al., 2014b).

The liberation of the social imaginary from the 20th-century developmental model that degrowth pursues implies an overcoming of the hyperseparation of society from nature (Plumwood, 2005), where expansion to satisfy social needs is seen as mastery over nature that then transgresses the boundaries of nature's biophysical systems—so that social needs and nature seem to stand in opposition. A degrowth society views stability and the ability to thrive, both of society and nature, as mutually reinforcing. It thus avoids the conceptually paralyzing trade-off between biophysical boundaries and social thresholds. Excesses and shortfalls exist in all dimensions of current socio-metabolic patterns: cultural, socio-economic, and biophysical. Understanding this allows us to envision integrated policies to keep the planetary human population within the safe and just operating space defined by known metabolic and cultural constraints of the 21st century (cf. *Mental Models of Sustainability: The Degrowth Doughnut Model*, this volume).

Policy Proposals for Socially Sustainable Economic Degrowth

Degrowth's double objective of achieving sustainable and just societies is primarily aimed at affluent societies. It is the affluent societies that should primarily downscale and redistribute, relieving other societies from the competitive pressures and allowing them to pursue their own different paths leading to that same double objective. If pro-environmental downscaling is implemented along with a redistribution toward greater well-being and equality, a substantial part of the population is likely to perceive it as socially acceptable (Ančić and Domazet, 2015). In affluent societies, it is not a higher level of income, but a lower level of inequality which leads to higher life expectancy and better educational attainment (Wilkinson and Pickett, 2011), and lower disparities in power and income lead to greater environmental protection (Boyce et al., 1999; Raworth, 2017, ch. 3). Therefore, a downscaling of the throughput must necessarily be accompanied by a monumental redistribution of resources and power—requiring all-encompassing democratic control.

In order to achieve this reduction in throughput with a parallel increase in well-being, degrowth proposes these policy measures:

1. *Economy and economics*: The economy has to be made substantive by capping resource use based on the limits imposed by the planet's biophysical boundaries, while human needs have to be democratically planned and equitably allocated to reflect those limits (Gerber and Scheidel, 2018). Sourcing of resources and products should be maximally localized. Economic production should focus on human livelihood and social reproduction, prioritizing relational goods over material goods, and placing sufficiency before efficiency and productivity. Advertising should be reduced and restricted.
Fractional reserve banking, the creation of money by private banks, and debt above what is needed for intergenerational redistribution should be abolished to limit the financial rents that drive the dynamics of growth. Concurrently, the state should take control over the issuing of "public money" (Mellor, 2010) to finance "a basic income or a job guarantee or to subsidize cooperatives, care services, environmental conservation or renewable energy" (Kallis et al., 2014, p. 13).
GDP as a measure should be abolished and replaced with indicators that measure social and environmental integrity through a multidimensional perspective of safe and just operating space (cf. *Mental Models of Sustainability: The Degrowth Doughnut Model*, this volume).
2. *Employment*: Lowering of economic output can lead to unemployment; however, the replacement of energy-rich fossil fuels might require more human labor (Sorman and Giampietro, 2013). Labor should be redirected toward care-work and social reproduction. Working hours should be reduced, work shared (Shor, 2014), and jobs guaranteed to anyone who seeks employment (Unti, 2014).
3. *Investment*: Investments should be redirected away from unnecessary and harmful activities such as military, fossil fuel, and polluting industries and toward achieving environmental sustainability in agriculture, technology, the built environment and infrastructure, financing public services, and supporting the development of a solidarity economy (Johanisova et al., 2014).
4. *Income and taxation*: Societies should establish a universal unconditional autonomy allowance (Liegey et al., 2013) and safe and complete access to basic goods such as food, housing, and care to meet the basic needs of all its members, while also placing a cap on maximum income and taxing wealth to limit disparities. Taxes should shift from taxation of labor to taxation of resources and pollution.
5. *Technologies*: Green technologies should replace polluting technologies to the degree that is feasible for the level of needs of a degrowth society. Gains in efficiency and productivity should be translated into caps on resources and reduction in working hours to prevent a rebound effect or the expansion of production. Technologies should be developed under open license arrangements and should be manufactured locally, while research and development should be done through a global collaborative effort (Medak, 2018).

6. *Restoration of ecosystems*: Downscaling the global throughput of energy and matter will not be enough to ensure planetary ecological stability—halting Earth’s sixth mass extinction as well as arresting anthropogenic climate change. Wherever they have been damaged, ecosystems need to be restored in order to effectively counter the destructive mechanisms already unleashed by the growth imperative. Expanding nature’s protected areas, afforestation, and replacing industrial agriculture with agroecological farming practices, are just some of the methods that can be used to serve this goal. Important as they are in and of themselves, these efforts also have the added benefit of shifting the social imaginary away from the current common sense of *Homo sapiens* as an inherently destructive species, to one that sees humans as inextricably tied to nature and capable of positive interactions with the nonhuman environment, in terms of fostering diversity and fecundity.
7. *Democracy*: Degrowth advocates for developing institutions of real democracy that extend and supersede the nominal democratic control that is prevalent in republican nation-states today. For instance, one vision of “direct democracy” that is gaining more traction within degrowth scholarship (Kallis, 2018; Vansintjan, 2018) is that of libertarian municipalism and communalism that was developed by Bookchin (2007) and Bookchin and Ursula (2015). Libertarian municipalism envisions a system of assemblies within differently scaled local areas, joining in a confederation of free municipalities. The broad consensus is that democratic practices and institutions need to be further developed and deepened from the currently dominant arrangement (Fraser and Jaeggi, 2018) and that economic democracy within workplaces is necessary (Asara, 2015). Since capitalism in all its forms has historically relied on institutional separations between the economic and political spheres (Cattaneo et al., 2012), a key condition for a degrowth transition is to reembed economic processes within the realm of social needs and political deliberation (Kallis, 2018).

Conclusion

The foundational insight of degrowth can be decomposed into three: there cannot be infinite growth of energy and matter throughput on a finite planet, economic growth cannot be decoupled from that throughput at the level of the global socio-ecological system, and the limits of planetary capacity to regenerate are already breached. Degrowth is a movement and a research framework which advocates for a societal transformation to reduce and stabilize, or “de-grow,” the energy and matter throughput of the global economic system, and to reorient economic activity toward designing structures of provisioning and peer-governance that address people’s shared and individual needs through flourishing of public wealth.

It is critical of the conception of economics and economic policy that disregard substantive determinants of economic processes like the metabolic interactions between society and the environment, politico-institutional structures, and the societal purposes of economic processes. It proposes to cap resource use based on the constraints imposed by Earth’s biophysical boundaries, and to democratically plan and equitably allocate common instruments of human needs satisfaction. Employment should be directed toward care-work and social reproduction, and investment directed toward ecosystems restoration and a solidarity economy. Economic production should place sufficiency before efficiency and productivity, ensuring sharing-driven provision for well-being. Societies should establish an unconditional autonomy allowance for all members based on the locally generated social surplus. Real democracy, where everyone interested has equal potential to participate in a collective process, should be the basis of decision-making, setting of boundaries, enforcement of rules and resolution of conflicts.

Abstract

Human activities are the main drivers of the Earth's ecological overshoot. Due to this overshoot, the actions of today may constrain the well-being of future generations. Simultaneously, despite the great extent and increase in economic activity, human needs are not universally satisfied. There is therefore a search for economic theories that offer answers to how to combine safeguarding of human needs with staying within the planetary boundaries. Here, four alternative economic approaches are reviewed. By combining insights from these, one may start to explore new territory and future pathways out of both ecological overshoot and human injustices.

Economic Growth and the Environmental Threat

The success in human development since the industrial revolution, including decreasing hunger rates, improved health, and scientific advances, gets much praise. This success has sometimes been attributed to the ability of the current civilizations to produce continuous economic growth, powered by free trade and globalization (see Fig. 1 portraying World GDP since year 1700 (Roser, 2013)) (Baumol et al., 2007). Nevertheless, we may still not live in the “best of all possible worlds.” What does it imply that World GDP has grown so tremendously?

The growth in world GDP is part of an unprecedented human expansion on Earth that is referred to as the *Great Acceleration* (Steffen et al., 2015). The notion of the *Great acceleration* suggests that the growth in economic activity is linked to a similar growth in environmental pressures and land system changes. Around 1700, nearly half of the terrestrial biosphere was wild and most of the remainder in the seminatural state. Today, due to land use expansion and intensification of land use, a majority of the land is agriculture and settlements, and only a quarter wild. Therefore, the contemporary forms and processes of terrestrial ecosystems are predominantly anthropogenic (Ellis et al., 2010). The current extent of human activities risks triggering biosphere tipping points across a range of ecosystems and scales (Lenton et al., 2019). Such tipping points threaten to undermine the life-support systems and lead to a less habitable “hothouse” climate state (Steffen et al., 2018). That would undermine any progress towards reaching human needs.

Fig. 1 World GDP from 1700 until today. From Roser M (2013) *Economic Growth*. Our World in Data. <https://ourworldindata.org/economic-growth>.

Furthermore, the needs of the current civilizations are not met. The evidences for this are many: hundreds of millions go hungry and lack the access to basic needs such as clean water (Ritchie and Roser, 2017; Roser and Ritchie, 2013). The inability of present societies to meet the basic needs of many is parallel to an accumulation of wealth in the hands of the few. According to a report from the British charity Oxfam, in 2018, 26 people owned the same wealth as the poorest half of humanity, consisting of 3.8 billion people (Oxfam, 2019). This, while around 800 million people or around 11% of the world population are defined as undernourished (Roser and Ritchie, 2013).

Economics, as a discipline, has set out as a goal to guide societies and this goal has been emphasized within the field. Paul Samuelson, an influential economist who 1970 received The Nobel Memorial Prize in Economic Sciences, has said, “I don’t care who writes the nation’s laws—or crafts its advanced treaties—if I can write its economics textbooks” (Samuelson, 1990). Furthermore, the economist John Maynard Keynes, famously wrote “The ideas of economists and political philosophers, both when they are right and when they are wrong, are more powerful than is commonly understood. Indeed the world is ruled by little else.” (Keynes, 2018, p. 340).

The contemporary economics discipline has been dominated by modern mainstream neoclassical economics, as virtually all university textbooks in economics are written from a neoclassical perspective (Fischer et al., 2018). This domination may be problematic as the same perspective has, combined with the neoliberal discourse, been argued to guide the world towards ever-increasing expansion and is continuing praising the virtue of exponential economic growth (Baumol et al., 2007; Göpel, 2016; Spash, 2017; Weil, 2009). Consequences of the downsides of today’s economies comprise both space and time dimensions of sustainable development. With other words, today’s societies are both failing to meet the needs and aspirations of current generations—and are simultaneously causing ecological problems that risk harming future generations. However, a diverse and growing group of academics is critically reexamining the current economic system and contribute to increased heterogeneity of world views in economics by offering alternative thinking.

The Root of the Problem

The ecological economist E. F. Schumacher argued in his book *Small is Beautiful* (1973) that economists often suffer from normative blindness and assume that economics is a science without presuppositions and is free from values. This is according to Schumacher (1973) a misstep as ideals of modernity, including considering consumption as the purpose of economic activity, influences the discipline. He makes a thought experiment by contrasting views on labor, standards of living, and patterns of consumptions prevalent in the economics discipline, against what they would be like if another point of departure such as Buddhist values would guide the discipline—and argues that these views are vastly different. Economic advises thereby reflect its normative starting points—and these are rarely presented or discussed (Schumacher, 1973).

Four Alternatives and What They Bring

Much of the critique against modern mainstream economics is not new (Daly and Townsend, 1993). Critics have recently, after the 2008/2009 financial crises, focused on inequalities within and between countries—and the increasing ecological crises. In the light of that humanity has entered the Anthropocene, there is a request for alternative economic paradigms that reflect this.

Below, a few more or less encompassing heterodox approaches to economic thinking that all bring different perspectives and tools for guiding the economy in a more sustainable direction, are presented. The four alternatives presented here are Post-Keynesian economics, Critical Institutional economics, Ecological economics, and System Dynamics. These approaches sometimes coincide with assumptions within mainstream neoclassical economics, and as there are many overlaps, there are not always clear distinctions between the different approaches.

This list of four alternative approaches is, of course, by no means exhaustive, and other approaches that deserve attention include Austrian economics, Evolutionary economics, Feminist economics and Marxist economics (see Further Reading).

Post-Keynesian economics

Post-Keynesian economics embarks from the British economist John Maynard Keynes’ ideas in his work *General Theory of Employment, Money and Interest* (Keynes, 2018) that he wrote as a reaction to the great depression. Post-Keynesian economics emphasizes distinct features of Keynes’ ideas, unlike the neoclassical synthesis that sought to incorporate Keynes’ ideas into neoclassical economics.

Post-Keynesian economics includes some assumptions which contrast it to modern mainstream economics and can contribute to the safeguarding of human needs within the safe operating space: it recognizes the contingency upon *historical time* as opposed to *logical time* used within mainstream economics, and it holds *deep uncertainty* as a fundamental building block of the economy, both explained below.

Mainstream neoclassical economics assumes *logical time*. Economic agents act rationally, expect others to act rationally and can thereby estimate the future. The assumption in Post-Keynesian is named *historical time*, according to which the behaviors of the world and individuals are constantly changing, and the past influences subsequent outcomes. Agents are, therefore, unable to figure out what the future is going to be. The past influences the future in unpredictable ways. This uncertainty influences planning and acting. In neoclassical economics, the future is probabilistic and risks can be calculated. Society could use this to insure itself, and by deciding on the risk preference, make an informed choice. According to this assumption, individuals and society can calculate and

plan for all future behavior at once. We can thereby, in line with for example (2018 awarded the Nobel Memorial Prize in Economic Sciences) William Nordhaus' model DICE, calculate and weigh costs and benefits of taking steps to minimize global warming and act rationally following its calculations (Nordhaus, 1992). Such a calculation is, from a Post-Keynesian viewpoint, troublesome as it reduces uncertainty to calculated risk and gives a false depiction of the world. In Post-Keynesian economics, neither the probabilities of, for example, a natural disaster, nor the expected outcomes, in the form of destructed buildings or suffering, can be meaningfully calculated. The world itself is unpredictable and constantly changing—there is *deep uncertainty* (Holt and Spash, 2009).

A consequence of the assumption of *deep uncertainty* in Post-Keynesian economics, is that an individual's behavior may be guided by the behavior of others causing so-called *herd behavior*. As these behaviors can radically transform, the result may be drastic and unpredictable fluctuations on financial markets. One example of this could be the estimations of the future price of a non-renewable resource such as coal. According to a mainstream economic standpoint, prices of coal would reflect its market supply effected by, among other things, its scarcity. As coal mines are being depleted, this would lead to higher mining costs and a lower supply which would drive prices upwards. However, this has not happened. Prices of coal do not reflect their absolute scarcity but rather the, according to Post-Keynesian Economics often irrational, expectations of market actors. A consequence of this is that market-based solutions to environmental degradation, or solutions including putting taxes on non-renewables, may not be effective. Price signals may be important but not sufficient to counteract unsustainable consumption. Instead, from a Post Keynesian perspective, the government has a responsibility to use a multiplicity of tools to counteract irrational fluctuations to limit the societal and ecological harm of an instable economy.

Critical institutional economics

Critical institutional economics (CIE) is another heterodox approach to economics. The main focus of the investigation is institutions in society. Institutions are defined as "systems of embedded social rule" (Hodgson, 2017, p. 45). This definition implies that institutions encompass laws, rules, and praxis as well as more soft norms prevalent in society. Institutional economics incorporates a broad school of thinkers, including those who are closer to mainstream economics as well as those who are more critical to mainstream economics. Those who are closer to mainstream economics typically study what is referred to as *market distortions*. A *market distortion* is when the situation differs from the *ideal market* that is given by perfect competition. The more critical streams of institutional economics bring insights from other disciplines in studying individual and collective behavior. These include insights on the limitations of individuals' rational behavior from psychology (behavior economics) and theories from philosophy, law, history, sociology, and political sciences.

According to CIE, society is shaped by an evolutionary process in which institutions affects the individuals and individuals, in turn, shape the institutions. Markets, which in mainstream economics are typically seen as a default arena that ensures the most efficient outcomes between individuals and for society, are in CIE seen as a result of interactions that can take different forms. The market prices in any economy, therefore, depend on existing regulatory frameworks and norms.

In mainstream neoclassical economics, it is typically assumed that individual preferences are pre-set and stable over time, and an economics investigation departs from individuals' so called *rational choices* between different consumer goods to maximize their expected satisfaction (referred to as utility). Equilibrium outcomes where the individuals' preference satisfaction is greatest are studied and seen as the logical outcome of individuals' behaviors. It is logical as individuals are seen as being always rational and typically narrowly self-interested. Critical institutional economic viewpoints criticize these assumptions for neglecting the specific institutional setting that frames individuals' preferences as well as the structure of the market. Individuals' preferences are also, unlike in neoclassical economics, in CIE not seen as stable but may change over time. CIE sees equilibrium outcomes as only some of many potential outcomes, and they are not necessarily the logical, nor rational, outcomes. CIE applies a more comprehensive view of individual behavior, which is combined with outcomes seen as emerging from interactions.

CIE views individuals' preferences as context-dependent and individuals' preferences, behaviors, and *rationality* may be affected by limited information, cognitive ability, and societal norms. Individuals possess *bounded rationality*, a term coined by Herbert A. Simon but more recently further developed within the subfield of behavioral economics notably by Tversky and Kahneman (awarded the 2002 Nobel Memorial Prize in Economic Sciences) (Kahneman, 2012). The behaviors of individuals affect institutions which feed-back on the individuals' behaviors.

Institutional economists see perceptions, interests, and power as influencing institutions. Power and interest protection are essential when explaining how economic structures like markets and firms are configured (Vatn, 2017). Neoclassical economics typically neglects this role of power.

An institutionalist analysis of the ecological overshoot may include that individuals act within an institutional structure with the norm to continuously strive for increased consumption. There is a conflict between an economic system with growth-demanding institutions and an environment that cannot handle the increased pressure (Vatn, 2017). The strive for increased consumption on an aggregate level, constitutes an unsustainable pressure on the planet. The unsustainable pressures are thus the outcomes of existing institutional structures. CIE policies to limit the ecological footprint do, therefore, not only entail pricing carbon emissions "right," a typical mainstream economics response, but instead seeing the bigger picture of the institutional normative setting and how it can be changed (including notable contributions from Elinor Ostrom (1990) who was awarded the 2009 Nobel Memorial Prize in Economic Sciences). However, we may neither be able to "get institutions right"—as the interdependency between institutions and individuals' behaviors are challenging to predict, and there is no easy way to find out or predict which institutions would be "right."

Also, a society's level of poverty and extent of inequality can, from an institutional perspective, be analyzed as an outcome of its institutions (Acemoglu and Robinson, 2012). Human needs are safeguarded by altering the institutions. The dynamics and evolution of power structures may, depending on the institutions, reinforce existing inequalities and exacerbate poverty. Thus, the fundamental policy issue includes what values and whose interests to protect (Vatn, 2017). Preferences can be deliberated and contrasted to each other, and different institutional structures may reflect or articulate different preferences.

Summing up, institutional economics invites taking a step back in analyzing alternative possible institutional arrangements and their potential effect on individuals' behaviors in line with sustainability. Critical institutional economics provide a perspective that extends the role of governments in providing the right frameworks to carefully analyze changes in norms, laws, and their effect on individual behaviors.

Ecological economics

With roots in ancient Greece and the definition of the world economy as "household," ecological economics focuses on the sustainable management of the world's resources. The current stream of ecological economics, however, took off in the 1960s and 70s when the study of energy and material flows, conceptualized as material throughput of society, came to the center stage of the ecological economists' economic analysis.

Ecological economics describes the economy as embedded in a natural system, see Fig. 2 (adapted from Giddings et al., 2002). Accordingly, the economy has to obey the rules of the biophysical reality within which it exists. Early ecological economists such as Georgescu-Roegen emphasized the need for economics to consider laws of thermodynamics (Georgescu-Roegen, 1993). The first law of thermodynamics includes that matter and energy can never be created nor destroyed within an isolated system. The Earth can be characterized as a closed system as it has a limited exchange of matter with the outside space while it exchanges energy. A consequence of that Earth is seen as a closed system is that the laws of physics constrain the size of humanity's material and energy throughputs.

That the natural system constrains the economy may be seen as undeniable when confronted with the Earth's biophysical limits, but is often overlooked by mainstream economics as well as by many heterodox schools of economics (Spash, 2017). It may be overlooked because the natural system is not considered as core to their analyses. From an ecological economist perspective, omitting this fundamental feature of reality may lead to conclusions and decisions that undermine the regenerative capacity of the biosphere on which the economy depends.

In the much-discussed book from 1972 titled *The Limits to Growth* (Meadows et al., 1972), the authors constructed a computer model to simulate possible futures of the human population. Their results highlighted the critical implications of the exponential growth of the human enterprise and the need to constrain it. One way to conceptualize humanity's aggregate impact on the environment prevalent in ecological economics is the $I = PAT$ equation which calculates the human impact on the planet (I) as a function of the size of the population (P) multiplied by the average affluence (A) and the resource intensity of current technology (T). According to this conceptualization, there are three ways for humanity to limit its footprint: by reducing the size of the population (P), by limiting wealth (A), or by greening the technology or change human behaviors (T). While the equation provides a rule of thumb for calculating the aggregated impact of human activity, it has been criticized for over-simplifying and not accounting for the more complex interrelations between the factors, and to be challenging to measure (Roca, 2002).

Ecological economics also discusses *absolute decoupling*. While some within ecological economics have argued that economic growth can continue while material throughput declines, the definition of absolute decoupling, others argue that it is neither possible nor desirable. The difficulty of decoupling economic growth and material throughput is often attributed to the rebound effect, also referred to as Jevon's paradox. Jevon's paradox states that as technology improves and becomes cleaner, the positive effect of the decreased emissions is counteracted by increased consumption as technology becomes cheaper. An illustrative example

Fig. 2 Conceptualization of nested sustainable development—the economy dependent on society and both dependent on the environment. Adapted from Giddings B, Hopwood B, and O'Brien G (2002) Environment, economy and society: Fitting them together into sustainable development. *Sustainable Development* 10: 187–196. <https://doi.org/10.1002/sd.199>.

relates to energy. Energy production efficiency improvements may initially cause both less environmental harm and lower energy prices. Over time, however, the efficiency gains may be counteracted by the lower energy prices—causing an increase in energy consumption above the initial level. *Relative decoupling* is another concept which denotes that the resource intensity of an economy may decrease per economic output. This concept is, however, not a relevant measurement as the absolute impact on the Earth is what is relevant for sustainability, not its relation to economic output.

The focus on biophysical limits or regenerative capacity of the planet, and the emphasis on constraining consumption for the sake of long-term sustainability, implies a principle of intergenerational justice. Ecological economists have also engaged with concepts of basic human needs to be guaranteed, and Georgescu-Roegen early emphasized the need to limit luxury consumption for the sake of providing basic needs for future generations. While natural scientists and economists have dominated ecological economics, there is a concurrent stream of ecological economics referred to as “social ecological economics,” which adds social and political factors to its analyses. Furthermore, building on ecological economics, the “degrowth critique” has stated that continuous economic growth is not only an environmental problem but also socially unjust as growth is no longer improving humans’ well-being in affluent societies (Spash, 2017).

System dynamics

Other valuable contributions to economic theories that combine the safeguarding of human needs while ensuring staying within the planetary boundaries embark from theories of complex systems. A complexity economics approach typically iterates between the behavior of individuals and the consequences of these for the behavior of social entities (Kirman, 2017). It does, however, rarely portray individuals as having complete information and acting in optimal ways to satisfy their narrowly defined preferences, as is the convention in mainstream economics. Nevertheless, unlike some other heterodox economic approaches that are critical to the use of formalized models, idealizations and reductions (Lawson, 2013)—complexity economics make use of models to simplify and idealize behaviors and explore “what-if” scenarios.

System dynamics is one complex systems approach used to analyze social phenomena that is being used by several schools of economic thought (Radzicki, 2011). It was developed from control theory, cybernetics, and the study of organizations in the 1960s and 1970s by Jay W. Forrester based at Massachusetts Institute of Technology (Forrester, 1961). The system dynamics approach defines a system as a set of things that are interconnected in such a way that they produce a particular pattern of behavior over time (Meadows, 2008). This definition includes three important features that characterize systems: things, interconnections, and time. The way different parts of the system are interrelated is assumed to be the essential factor that explains system behavior. System dynamics interprets these interrelations as causal links between the system components. Causal links are mapped in order to communicate imagined system structures. The system dynamics tradition offers mapping tools (such as causal loop diagrams and stock and flow diagrams) where different assumptions and views can be portrayed and subsequently discussed.

From a system dynamics viewpoint, the ecological overshoot can be attributed to the systems characteristics of the world economy—as it is the causal structure that drives the behavior—and represented by a series of causal chains and loops.

The systems diagram in Fig. 3 portrays a conceptualization of how production depends on a reinforcing loop, and a counteracting loop of social-ecological collapse. Production is at the center of the diagram as it enables the provision of people’s needs required for human well-being. The production also, through the required material throughput, links to pressures on planetary boundaries—with the risk of social-ecological collapse that follows (Collste et al., 2018; Randers et al., 2019).

In Fig. 3, the R1 reinforcing loop causes exponential growth in production through capital accumulation (*production* enables investments in *physical capital* that increases the *production capacity*). This loop is combined with a delayed counteracting loop that risks causing a global social-ecological collapse (an increase in *production* leads to increased *material throughput* that implies *pressures on planetary boundaries*—with the risk of a *social-ecological collapse* undermining further *production*) (Collste et al., 2018). To find alternative futures following the system dynamics approach, one would iterate between model structure and its behavior and analyze different model structure hypotheses and their relationships to reality.

Poverty and inequality are from a system dynamics viewpoint typically seen as the results of a system structure that may lock people in poverty. In this case, the economic success of an individual, family or group of individuals may be self-reinforcing. Lack of economic success can be attributed to the opposite dynamics or a poverty trap perpetuating multidimensional poverty and such system traps exist in various forms and are difficult to escape (Lade et al., 2017).

Meeting Basic Needs and Living Within the Safe Operating Space

The abovementioned heterodox approaches can provide complementary insights to the problems of unmet human needs and ecological overshoot. As Post-Keynesian economics emphasizes that markets often behave irrational and brings the adherence to deep uncertainty, it highlights the need for an active role of governments in directing the economy. This argumentation extends the role of government in promoting human well-being and ecological sustainability, in contrast to narrowly focused market solutions. The Post-Keynesian approach can be combined with the institutionalists’ emphasis on the role of the institutional frameworks in minimizing poverty and human exploitation. Ecological economics provides the ecological guardrails to human development and pinpoints the need to incorporate the biophysical reality in the development of economic institutions. Ecological economics also emphasizes the need to keep conspicuous consumption low not to undermine the living conditions of future generations. It thereby bridges economy and ecology. System dynamics, in turn, offers mapping tools and simulation models that invite to the examining of different hypotheses.

Fig. 3 Conceptual sketch of the Earth3 model used in the [Randers et al. \(2019\)](#) report. From Collste D, Randers J, Goluke U, Stoknes PE, Cornell S, and Rockström J (2018) The empirical bases for the Earth3 model: Technical notes on the sustainable development goals and planetary boundaries [preprint]. *EarthArXiv*. <https://doi.org/10.31223/osf.io/ephfs>.

The future of humanity and its dependence on a flourishing biosphere is at a crossroads. The current way of structuring the economies has resulted in an aggregated size of the world economy that threatens the health of the planet's life-support systems. Simultaneously, human needs are not universally met as many people are hungry and inequalities are extensive. This precarious situation has led to a search for alternative economic paradigms that can provide answers to how to combine the safeguarding of human needs with life within planetary boundaries. This contribution presents four alternative approaches that may contribute to finding ways forward. By combining insights from these, it is possible to explore new territory and future trajectories away from human suffering and ecological overshoot.

Post-Keynesian economics pinpoints the need to consider deep uncertainty and the possibility of governments to intervene to ensure that human needs are met. Ecological economics sets the ecological and biophysical frame within which development has to take place. Institutional economics offers critical analyses to examine how institutions affect human behavior and how human behavior feeds back on institutions. System dynamics, in turn, offers practical tools to critically examine the coherence of different perspectives and explore what-if scenarios by simulation.

To conclude: "There is too much bad news to justify complacency. There is too much good news to justify despair." ([Meadows, 2008](#)). The search for alternatives has just begun.

Further Reading

The critique against modern mainstream economics goes back in history (see *Valuing the Earth*, Ed. [Daly and Townsend \(1993\)](#) for a collection). The critique has gotten renewed attention, see for instance [Trebeck and Williams \(2019\)](#), [Raworth \(2017\)](#), [Jackson \(2011\)](#), [Spash, 2017](#), and [Victor \(2019\)](#).

Abstract

Values is a central concept to the study of human behavior and conservation policy, but its meaning tends to vary throughout academic literature. This poses a challenge, as scholars operating from different definitions of *values* tend to talk past each other, resulting in widely varying recommendations for effective conservation policy. The purpose of this article is to elucidate the assumptions in academic literature about how values shape human behavior in the context of conservation. The article compares the working definitions of values in economics, anthropology, and philosophy, and how these fields treat the concept of *valuation* or the assessing of values for incorporation into policy. I review how conservation policy historically has been influenced by varying assumptions about how values shape behavior, and I show how this has resulted in conflicting recommendations for how policy should appropriately target human values. Finally, I conclude with a summary of contemporary understanding of conservation values and state of the art recommendations for effective conservation policy design and implementation.

Introduction

David Graeber, in his 2001 book *Towards an Anthropological Understanding of Values* begins with the following passage:

"If one reads a lot of anthropology, it is hard to escape the impression that theories of value are all the rage of late. One certainly sees references to 'value' and 'theories of value' all the time – usually thrown out in such a way as to suggest there is a vast and probably very complicated literature lying behind them. If one tries to track this literature down, however, one quickly runs into problems. In fact, it is extremely difficult to find a systematic 'theory of value' anywhere in the recent literature; and it turns out to be very difficult to figure out what body of theory, if any, that any particular author who uses the term 'value' is drawing on. Sometimes, one suspects it is this very ambiguity that makes the term so attractive" (1).

The same statement seems to apply to the academic publications on conservation policy. Statements about human behavior and the efficacy of policy address values in the abstract, but are often working under varying assumptions of what values are and how they relate to human behavior. The understanding of values is central to the ability to create effective policies, as values shape humans' understandings of the world, and our actions in it. We know people do things for a reason, and values appears to be that reason. Hence, any hope of effective policy mechanisms must engage with, and potentially alter values to be effective.

But, are values concrete or abstract? Are they generally stable or fluid? And how do they interact with conservation policy to alter human behavior in favor of a more sustainable planet? It turns out that these central questions are unresolved in the literature. Nonetheless, numerous studies have been chipping away at the topic from different angles.

This article engages with the various definitions of values as they pertain to conservation policy, and how these definitions have shaped policy historically and into the present. I begin by tracing the definition of "values" across a few principle threads in academic literature—namely psychology, economics, and anthropology, as these fields represent the breadth of the developed literature on *values* and they have been implicitly and explicitly informing conservation policy for decades. Although there are countless other ways to explore the concept of values, the intention here is to provide a general characterization of commonly employed understandings, and not an all-inclusive account of the literatures. I will then proceed to outline various conservation approaches in terms of what each assumes about values, and how related policy mechanisms utilize concepts of values. Finally, I will discuss how policy itself shapes value systems, and the implications of contemporary conservation policy for "conservation values" more broadly speaking.

Values and Valuation

Foundational work by Rokeach (1973) in psychology describes a value as "an enduring belief that a specific mode of conduct or end-state of existence is personally or socially preferable" to an alternative (p. 5). He differentiates these from value systems, which

he describes as “an enduring organization” of these values (p. 5). Though using different terminology, both psychologists and anthropologists have concluded that values are created through culture (Hofstede, 1984; Polanyi, 1957; Schwartz, 1999), with anthropologists highlighting that they are expressed and reproduced by action (Graeber, 2001; Munn, 1986). From this perspective, values guide action and determine human behavior (Rokeach, 1973; Schwartz and Bilsky, 1987).

There is another definition of value, however, that tends to muddle the above understanding. That is the concept of the value of things, or the “qualities inherent in objects” (Schwartz and Bilsky, 1987, p. 550). Much of this confusion stems from economic theory, where theorists argue that human action is motivated by the value of objects, and through self-interested behavior, market efficiency is realized. Market efficiency then maximizes total *value* to society by producing the greatest amount of social good (Jevons, 1866). The value of objects, according to this line of thinking, is reflected in price, or *exchange value*. This conceptualization of values results in a bit of a tautology—an object of high value (price) is valued because it increases societal value (utility), as determined by values (preferences) (see Broome (1991) for an elaboration on this topic)! The murkiness of terminology presents a challenge for conservation praxis when the exchange or economic value of an object or scenario, often the target of a particular policy, becomes conflated with human values (social preferences that guide action) and the two are treated as interchangeable.

If the goal of policy is to maximize social well-being, then implementing policy requires the ability to compare the values of alternative policy scenarios, and make choices based upon these values. In a market setting, economists argue, price is reflective of societal value. Therefore, economists use *valuation*, or estimating the value associated with goods and services, to help predict the impact of different policies. Because environmental goods and services typically are not traded in competitive markets, economists have developed nonmarket valuation techniques to estimate the exchange value of the environment for comparison to market goods. There are a variety of techniques that fall into this category. The indirect techniques of travel cost and hedonic modeling rely on market values that can serve as proxies for environmental goods, such as the amount of money spent to travel to a recreation area, or the price for a house that includes environmental amenities (Champ et al., 2003). Stated preference methods, in contrast, are techniques that rely on surveys that ask individuals to state their willingness to pay (WTP) or willingness to accept (WTA) compensation for changes in environmental services (Adamowicz et al., 1998). Nonmarket valuation allows for subsequent incorporation into cost benefit analysis, which can be used to guide policy. Though nonmarket valuation methods have been critiqued for their inaccuracy (Spangenberg and Settele, 2010), best practices are continually being developed to limit these deficiencies (Carlsson et al., 2007), and economists assert that imperfect valuation is still preferable to no valuation.

The economic understanding of value has heavily influenced conservation science, and conservation scientists have spent the last 20 years trying to precisely measure of the value of nature (Costanza et al., 1997; Daily et al., 2000). Conservation scientists have worked with economists to estimate the value of numerous aspects of environmental management, such as the value of hemlock woolly adelgid management in eastern hemlock forests (Poudyal et al., 2016), or the value of different land management regimes in producing ecosystem services across a watershed (Nelson et al., 2009). Such efforts employ the economic understanding of value, and the techniques of nonmarket valuation, in an attempt to convince policy makers of the value of the environment.

In contrast, anthropologists have tended to argue that values are embedded in social systems (Polanyi, 1957), where they are produced by and reflected in cultural institutions and relationships (Munn, 1986). It follows from this line of logic that economic activity and human decisions cannot be understood as independent from social systems (Dalton, 1961; Sahlins, 1972), and exchange value is only one facet of *value* that has arisen to predominance in a capitalist system (Graeber, 2001). Therefore, any attempt to understand human behavior in an economy needs to understand the entirety of the system within which individuals interact.

The understanding of values as culturally embedded relates to a term that is gaining traction in conservation and environmental circles—that of *relational values*. The idea captured by that term is that values are shifting and context dependent (Pascual et al., 2017). From this perspective, values are constructed in relationships—food might be valuable from a sustenance perspective, but it is also valued for cultural roles, and the social connections fostered through food production, preparation, and sharing (Chan et al., 2016; Klain et al., 2017). This concept mirrors the idea of embedded values in anthropological terms, whereby values cannot be abstracted from the systems within which they are created (Polanyi, 1957). Hence, any attempt at valuation must understand the entirety of the context, and multifaceted approaches to detect multiple value systems are needed (Jacobs et al., 2016).

Those advocating for an understanding of values as relational and embedded have tended to challenge economic valuation. Anthropologists have asserted that economic valuation reduces the multitude of human values to a simplistic, and often ironic, monetary exchange value (Graeber, 2001). Other scholars and conservation activists have raised concerns about placing a monetary value on the environment (Goulder and Kennedy, 2011). The key arguments against such techniques are that they undermine the total value of nature (McCauley, 2006), and that they are inappropriate given the complexity of natural and social systems (Kosoy and Corbera, 2010; Spangenberg and Settele, 2010). For example, many scholars adhere to the idea that environmental values are inherently incommensurable—exchange values do not represent the full complexity of environmental values, such as biodiversity value of species, and aesthetic value of amenities (Martinez-Alier et al., 1998; Norton and Noonan, 2007). Inappropriate valuation may provide a solution to conservation ailments with unforeseen social and ecological consequences because they undermine relational value systems that are crucial for sustainability (Jax et al., 2013; West et al., 2006). Given these challenges to valuation, scholars have suggested that the next step forward should involve understanding the interactions and tensions among values across scales (Díaz et al., 2015), and incorporating a diversity of values into policy (Chan et al., 2017).

How values are understood and “measured” is more than an esoteric discussion, it has real implications for environmental policy design. If values are absolute, and able to be abstracted from social context, then we can hope to effectively identify, target, and design universal policies that people will respond to in predictable ways. Economic valuation would then be critical to

estimating these values for subsequent incorporation into policy, and environmental degradation would require fixing the market via a series of Market Based Conservation Mechanisms or Market Based Incentives. However, if values are relational, then policy must always be context-dependent and nuanced. In this case, policy would need to focus on the establishment and maintenance of effective institutions to mediate environmental behaviors (Dietz et al., 2003). Conservation policy throughout the last 50 years has vacillated among these assumptions about human values, resulting in extreme variation in claims of policy efficacy, as well as varied approaches to conserving the *value* of the environment.

Conservation Policy—A Brief History

Conservation has shifted focus in the last 50 years from the accumulation of protected areas to the sustainable management of multifunctional landscapes (Mace, 2014), and beneath this shift there have been continual battles over appropriate policies and related framing of human values. Prior to the 1980s, conservation was primarily focused on land acquisition—the need to set up protected areas safe from deforestation and environmental degradation (Terborgh, 2004). Protected areas limited human access in favor of the preservation of biodiversity, often forcibly removing humans in their establishment (West et al., 2006). This early conservation endeavor was inspired by the “crisis-driven” nature of conservation, namely that available land needed to be preserved before it was too late (Soulé, 1985). Much of the focus during this phase was on preserving tropical areas and biological hotspots, which were presumed to both house more biodiversity and provide greater return on conservation dollars invested, given the relatively cheaper cost of land in many tropical countries (Myers et al., 2000). Continual developments in ecology, including metapopulation ecology and landscape ecology, identified the need to increase the scale of conservation because biodiversity maintenance required large tracts of connected habitat for population migration (Saunders et al., 1991; Turner et al., 2001). Conservationists recognized that the preservation of isolated protected habitats alone was insufficient to prevent biodiversity loss, and they accordingly shifted focus to landscape scale conservation under the paradigm of biological corridors, mixed-use landscapes, and transboundary protected areas (Townsend and Masters, 2015).

The shift in focus from protected areas to landscape conservation occurred in tandem with an increasing concern among academics and policy makers for human rights. Protected area conservation received extensive criticism from social scientists and human rights activists because park establishment frequently involved the forced removal of humans from within their boundaries, relegating former inhabitants to poverty while denying them access to natural resources necessary for survival (West, 2006). For example, Dan Brockington documented the process through which the creation of the Mkomazi game reserve in Tanzania caused the forced removal of several pastoral tribes from the region, permanently affecting their livelihoods (Brockington, 2002). Scholars further revealed that conservation, though often perceived as solely altruistic, was inherently political and deeply rooted in colonialism—redefining who had access to nature and under what uses (Adams, 2004). Similarly, government officials expressed concern that conservation stymies economic growth because it conflicts with development goals (Malik, 1982). The combination of these voices resulted in a shift in conservation agenda; increasingly, human rights interests became intertwined with global conservation policy (Phillips, 2003).

As human rights and landscape planning moved to the forefront of conservation, the concept of sustainable development arose as the way to meet conservation imperatives while improving human well-being (Bruntland, 1987). Though the term has been critiqued for its vagueness, it addresses the development goal of increasing human well-being across world populations, while emphasizing that environmental resources are finite and integral to the survival of future generations (Lélé, 1991). In practice, sustainable development policies have typically aimed to promote economic growth through encouraging livelihood activities that purportedly operate in harmony with the natural environment. Early sustainable development initiatives promoted nonextractive employment opportunities around parks through the implementation of Integrated Conservation and Development Programs (ICDPs) (Wells et al., 1992), and community control of natural resource management (Brosius et al., 1998). Examples of such initiatives include limiting activities in buffer areas in exchange for development infrastructure (Wagner, 2001), ecotourism within protected areas (Aylward et al., 1996), and community management of sea turtle reproductive sites (including sustainable egg harvest) (Campbell, 1999). Though widely differing in implementation, such initiatives shared in common the philosophy that ecological sustainability depends upon the economic well-being of local populations, and that conservation, if appropriately supported, would ensue under community management (Western and Wright, 1994). Such programs demonstrated mixed results, however, in part due to the complicated nature of communities, and the challenges of scaling ICDPs under the imperative of landscape conservation (Berkes, 2007).

These early initiatives evolved into the contemporary discussion of ecosystem services, whereby the economic sustainability of society is depicted as dependent upon ecosystem health (Costanza et al., 1997; Daily et al., 1997). Ecosystem services classify human benefits, such as water filtration and carbon sequestration, received from ecosystems (Daily et al., 2000). Scholars advocating this concept contend that it will assist in bringing ecosystem values into environmental planning to ensure long-term sustainability (Christie et al., 2012; Engel et al., 2008). The implication is that “win-win” situations can be realized via spatial planning for ecosystem services (Kareiva et al., 2011). However, this requires that values for ecosystem services can be effectively identified and targeted (Wünscher et al., 2008), and that ecosystem services are not in competition with each other across scales (Nelson et al., 2009). Furthermore, effective policy must appropriately target ecosystem service values and adequately alter human behavior across diverse social-ecological contexts.

In the face of continual reduction in biodiversity, bordering on a mass extinction (Ceballos et al., 2015), conservationists seek solutions that are scalable and translatable (Kremen et al., 2000). Market-based Conservation Mechanisms (MBCM) arose to prominence in this context because they purport to offer a cost-effective means of conservation with greater flexibility in implementation than prescriptive policies (Ferraro and Kiss, 2002). These instruments tend to treat ecosystem services as fungible units of value that are transferable across spatial and social scales (Boyd and Banzhaf, 2007). The allure of these approaches is essentially scalar—we can assume that one-size-fits-all will work with enough data to appropriately shape policy. This is seductive for conservation scientists, practitioners, and organizations, who are pressed to find a solution to an ever increasing global environmental crisis.

MBCM commonly refer to any policy mechanism that uses price signals to correct market-failure, in contrast to prescriptive (command-and-control) policies (Pirard, 2012). Though in practice these mechanisms often fall short of establishing actual markets for the trading of environmental goods, they are often deemed “market-based” because they attempt to change behavior by targeting the economic value of ecosystem services (Corbera, 2015; Fletcher and Breitling, 2012). Furthermore, suggestions for improvements on existing market-based instruments frequently point to the need to make them more market-like (Jack et al., 2008). Taken from this perspective, the current state of market-based conservation policies can be seen as an evolution of policies that have been proposed under the explicit goal of becoming increasingly more market-like, thereby providing an efficient means of conservation (Gómez-Baggethun and Muradian, 2015).

MBCM have evolved from taxes and subsidies to trading schemes and payments for ecosystem services (Field and Field, 2002). Popular contemporary MBCM include direct markets, certification schemes, mitigation banking, carbon credits, and payments for ecosystem services (PES). Direct markets and certification schemes use marketing to finance the preservation of environmental goods and services. This includes nature tourism and ecotourism markets (Stronza and Durham, 2008), sustainable tourism certification programs (Honey, 2002), as well as environmentally amenable agricultural practices, such as rainforest alliance coffee (Auld, 2010) and organically produced agriculture (Zanoli et al., 2013). Carbon credits are a cap-and-trade system that allow carbon emitters to trade carbon permits on an open market, thereby maximizing the efficiency of carbon emissions and mitigation (Sorrell and Sijm, 2003). PES programs are a broad category, and perhaps one of the most popular of these mechanisms. These programs attempt to create markets for ecosystem services and identify exchange values for environmental goods so that providers of ecosystem services can receive monetary compensation from ecosystem service users (Wunder, 2005). REDD is a United Nations program that takes the concept of PES and applies it at an international scale, providing international funds to support conservation and carbon sequestration in developing countries (Culas, 2012).

These various conservation policies have occurred in tandem with shifting debates about the relationship between human behavior and value systems. Each of the above conservation approaches has an accompanying argument about human values and human behavior that undergirds its rationale. Unfortunately, these assumptions have typically been implicit, and not subjected to critical review that provides a better understanding of the strengths and shortcomings of each.

Conservation Policy and Conservation Values

Protected area approaches tend to adopt a utilitarian framing of value systems, in which values are fixed, absolute, and humans are subject to “the tragedy of the commons” in their interactions with the natural world (Hardin, 1968). In this framing, those needing natural resources consume and degrade the landscape in a drive to maximize individual utility. Protected areas, monitored by guarded forces, were a logical response to this threat. The only way to stop the public’s innate drive to degrade the land was to separate humans from nature.

Community-centered conservation approaches vary in their framing of value systems, and perhaps have been appealing because those who frame values as utilitarian, and those who consider values as relational in nature can accept them. By using the term “community-centered,” I broadly reference the policy approaches that attempt to include locals in natural resource decision-making, allocation, and management. This would include many ICDPs, Community Based Conservation, Community Based Natural Resource Management, and other grassroots programs. Collectively, they share Elinor Ostrom’s framing of the natural resource allocation problem, whereby institutions can effectively moderate natural resource degradation, as long as they share effective properties (Ostrom et al., 1999). From a utilitarian perspective, communities value natural resources because they are a form of natural capital, whereby they can be converted to other forms of capital to maximize well-being. Through supporting the effective management of these resources by local communities, the conservation movement is supporting their livelihoods, and will therefore garner more support for protected areas, and conservation as a whole (Kareiva and Marvier, 2007). Conversely, a relational values framing also maps onto these approaches—whereby locals’ complexity of knowledge and uses of natural resources, as well as the complexity of relations with the environment, make them potentially *more effective* environmental managers (Brechin et al., 2002). The key from this perspective is that effective community-centered conservation requires engagement with local communities to support complex existing environmental values, and better align these values with conservation efforts (Brosius et al., 1998).

The ambiguity in terms of value framing, however, has turned out to be a weakness of community-centered conservation and has led to its decreasing popularity throughout the start of the 21st century. Those adhering to a relational values framing have tended to argue that programs need to devolve more authority to local communities (Borrini et al., 2004; Campbell and Vainio-Mattila, 2003), while the utilitarian camp tends to advocate for more careful monitoring of resources because locals will tend to over

consume them to support livelihoods (Robinson, 1993; Terborgh, 2004). To complicate this problem, community-centered approaches proved expensive, difficult to monitor, and slow to progress (Berkes, 2004).

Through the ecosystem services framing of environmental values, a utilitarian construct rose to prominence, and community-centered approaches fell out of fashion (Gómez-Baggethun et al., 2010). Economists rooted in neoclassical theory characterize environmental degradation as an example of market failure, where optimal individual decisions do not create optimal social outcomes (Hanley et al., 1997). Market failure exists because the benefits provided by the environment are external to the market and do not factor into private decisions (Gordon, 1954). The solution, from this line of reasoning, has been to propose MBCM that can internalize ecosystem services (externalities), bringing their costs into decision-making. In contrast, numerous scholars have argued that the continual, exponential growth of the market-system itself is the underlying culprit of environmental degradation (Matulis, 2014; McAfee, 1999). These scholars argue that not only will MBCM not work, because they will not appropriately target values, but that through focusing on exchange values they promote a focus on short term-profits that will actually erase the remaining value structures that might be necessary to support conservation into the future (Acheson, 2000).

Conservation Values and Motivational Crowding

This argument speaks to a parallel debate, originating in behavioral economics, concerning the nature of monetary incentives and whether they “crowd-in” or “crowd-out” intrinsic motivation. Frey and Jegen (2001) summarized this literature, demonstrating that monetary incentives either crowd-in (strengthen) or crowd-out (weaken) intrinsic motivation. In other words, monetary incentives themselves appear to change value systems. This literature described case-studies where the nature of the incentive seemed to be particularly important. For example, if altruism was key to the behavior in question, then monetary incentives tended to crowd-out intrinsic motivation because participants began to view the service as something belonging in the economic sphere (Frey and Oberholzer-Gee, 1997). Furthermore, the crowding-out effect became predominant when people recognized a payment as infringing on self-determination. The findings are critical to the role of MBCM, as environmental stewardship is typically undertaken by individuals who are other-regarding, and sense a deep connection to the natural environment (Bramston et al., 2011).

Of MBCM, the most research has been done on motivational crowding in PES programs. Currently, there is a lack of consensus in this literature, though most studies seem to point toward a general caution with the use of economic instruments because of unforeseen interactions with value systems (Neuteleers and Engelen, 2015; Rode et al., 2015). Some studies have found that economic incentives crowd out environmental stewardship (Agrawal et al., 2015; Frey and Oberholzer-Gee, 1997) as they can undermine morality and serve to justify behaviors that might otherwise be unjustifiable (Bowles, 2008). In a review of 50 studies, Bowles and Polania-Reyes (2012) found that when market-like incentives were instituted, in 69% of cases they showed crowding out. They argued that these incentives often trigger a “moral disengagement” and that general social preferences will determine how people respond to economic incentives (p. 390). Further studies have shown that whether an incentive crowds-out or crowds-in intrinsic motivation depends on local context (culture), and individual personality (De Martino et al., 2017; Rode et al., 2015; Van Hecken et al., 2017). Because economic incentives do not result in predictable impacts, the best approach is caution moving forward (Allen and Colson, 2019). If economic incentives run the risk of changing value systems with regards to the environment—they leave “ecosystem services” subject to funding from a volatile market that is accustomed to receiving these services for free (and using them to fuel economic growth). This is particularly challenging, as economic markets do not operate on the same time scale as ecosystems, and policies designed to finance environmental protection might find themselves gutted when markets shift (Allen, 2018).

Though inconclusive, this literature has successfully challenged MBCM to the point that many analysts currently advocate for an integrated approach to policy design and valuation. It seems clear that monetary valuation is not reflective of the complex value systems that inform environmental behavior (Garmendia and Pascual, 2013). Further, despite ample efforts, it is exceedingly difficult to design and support conservation markets—these markets are not as “hands-off” as many once hoped, and they are not clearly increasing ecosystem services (Wunder et al., 2008). As a result, monetary valuation should be a small part of a whole suite of tools used to assess environmental values, and design appropriate policies (Jacobs et al., 2016).

Conclusion: Policy and Value Pluralism

Given the state of conservation as described above, how do we move forward to protect what remains of biodiversity on an increasingly globalized planet? If one thing is salient from the literature examining human values and conservation behavior, it is that context matters. Individuals respond in nonpredictable ways to institutions. Economic incentives may have the intended effects on occasion, but their design rests on assumptions about human value systems that do not necessarily hold outside of the market sphere (Bowles and Polania-Reyes, 2012; Gowdy et al., 2009). On the other hand, mandatory enforcement and government intervention in natural resource use has resulted in human rights violations and continual environmental degradation. So how to move forward?

If people behave in context-dependent ways, uniform policy may be impossible. A diverse suite of policies will be necessary at the local scale to support both heterogeneous multifunctional landscapes and heterogeneous value systems. Increasingly, scholars are finding that perhaps policy has not put enough faith in communities (Gavin et al., 2018). Engaging more effectively with communities might require supporting grassroots initiatives, environmental education, and local markets. Other approaches to

engage with communities might include restructuring PES and REDD programs to meet local needs and inspire collective action (Pfaff et al., 2019). Despite the hopes of one-size-fits-all policies that can easily translate across scales, this review suggests that future policies will need to be flexible so that they can engage communities and mold to local contexts. This might make conservation more challenging, but ultimately, it will likely make it more effective.

Abstract

Human actions have consequences that affect many other species of animals and plants and even nature itself in ways that cause both significant harms and benefits. We must take account of these consequences and evaluate our conduct in light of them by broadening the scope of our ethical thinking. This is especially important in light of the shift in ecological thinking toward an understanding of the terrestrial biosphere in terms of anthropogenic biomes or anthromes. The striking ways in which human beings have changed and continue to modify global ecological patterns into these distinct anthromes calls for a critical understanding of how ethical principles and values apply to them. The purpose of this article is to provide several ethical frameworks that enable us to establish reasonable ethical values for managing anthromes and principles for evaluating the human conduct that creates and modifies them. The article considers in more detail the way in which the scope of ethics has changed in response to concerns about the moral implications of human interactions with the natural environment. It examines the question of what has value and what the source of this value is. The discussion of value leads to a basic understanding of what it means to value anthromes. Finally, the article examines three different ethical frameworks that may be used to value anthromes. These are descriptive moral psychology, traditional ethical theory, and environmental sustainability. As the scope of ethics has enlarged over time, the role of ethics in valuing anthromes has gotten correspondingly more complex.

Introduction

Ethics is the intellectual study of the most fundamental guidelines for human action. Ethics establishes norms for human behavior in all those contexts in which human beings can cause significant benefit or harm to others. It includes virtues such as generosity and justice, rules such as do not cause unnecessary pain or harm, rights such as the right to life, and values such as goodness and happiness. These norms serve both to direct action toward what is good and to evaluate actions as right or wrong, permissible or impermissible, obligatory or forbidden. In the past, it was customary to restrict the scope of ethics to human beings and their individual actions, but that is no longer possible. Human actions have consequences that affect many other species of animals and plants and even nature itself in ways that cause both significant harms and benefits. Consequently, we must take account of these consequences and evaluate our conduct in light of them. Broadening the scope of ethics is especially important in light of the shift in ecological thinking toward an understanding of the terrestrial biosphere in terms of anthropogenic biomes or anthromes. The striking ways in which human beings have changed and continue to modify global ecological patterns into these distinct anthromes calls for a critical understanding of how ethical principles and values apply to them. The purpose of this article is to provide several ethical frameworks that enable us to establish reasonable ethical values for managing anthromes and principles for evaluating the human conduct that creates and modifies them.

The first part of this article considers in more detail the way in which the scope of ethics has changed in response to concerns about the moral implications of human interactions with the natural environment. It examines the question of what has value and what the source of this value is. The discussion of value leads to a basic understanding of what it means to value anthromes. The next sections of the article examine three different ethical frameworks that may be used to value anthromes. In brief, these are descriptive moral psychology, traditional ethical theory, and environmental sustainability. As the scope of ethics has enlarged over time, the role of ethics in valuing anthromes has gotten correspondingly more complex.

Ethics and the Natural Environment

For most of its history ethical discussion has focused only on conduct as it related either directly or indirectly to human beings. From this perspective actions that significantly benefit or harm other persons clearly fall under the purview of ethical thought. Actions that

affect animals, plants, and nature, however, do not unless these actions indirectly benefit or harm other persons. For example, killing an animal for food is not wrong in itself. It would only be wrong if killing the animal for food causes a harm to another person. It is permissible for me to kill my own chickens for food. I could not kill someone else's chickens for food, however, for the same reason that I could not damage their property. This would indirectly be a harm to them. Similarly, polluting a river would not be wrong because of the damage it does to the river and the fish and other animals that depend on it for life. It would be wrong only if this pollution caused harm to human life. The term for this ethical perspective is *anthropocentrism*. According to anthropocentrism ethical principles guide actions that have consequences for human beings. Ethical concerns about anything else are valid only if they can be traced back in some way or other to human concerns.

It is understandable and to a certain extent natural that the scope of ethics should begin with the consideration of human interests. But in light of our affinities with other species it would be surprising if it should end there. Accordingly, many ethicists believe that the scope of ethics must be extended in various ways. Some argue that it should be enlarged to include all sentient beings because they can feel pleasure and pain. Others argue that pain and pleasure are adaptive characteristics of living beings and thus an arbitrary way to limit our ethical deliberations. For them the scope of ethics needs to include all living beings. Yet others who emphasize the interconnections and interdependencies within ecosystems argue that these ought to be included in the scope of ethics as well. These considerations apply generally to the role of ethics in valuing anthromes. From them we may conclude that it is reasonable to speak of the value that anthromes themselves have and of the value of all those beings which inhabit them. There is argument about how to assign appropriate value to those things that fall within the scope of ethics, but it is absolutely important not to begin by excluding things. The role that human beings now have in shaping ecological patterns makes it even more imperative that we extend our awareness of all the ways in which our actions may benefit or harm other things: other human beings, other sentient beings, other living beings, and even the biophysical ecological systems upon which we all depend.

When we do examine the value things have, it is important to distinguish between instrumental value and intrinsic value. Intrinsic value is the value that something has in itself. Instrumental value is the value that a thing has because it leads to something else that has value. When we are sick medicine has instrumental value because it leads to health, which we value. Health has intrinsic value. This distinction relates to the previous discussion in the following way. According to anthropocentrism, only human beings have intrinsic value. Everything else that has value is valuable because it contributes instrumentally to human well-being. Other animals and plants are valuable only because they enable human beings to live well. Similarly, on this view, anthromes have value only because they are the ecological support for human life.

Our dependency upon other animals, plants, and the biomes of which we are a part does mean that these things have instrumental value for us. It does not follow, however, that this is the only value that they have. It is not unreasonable to believe that other living things and even biophysical systems have intrinsic value. What this value is and what it may be based on are important matters that should be decided as part of an ongoing ethical discussion, not excluded from the beginning of it. We need to be open to the possibility that things have value independently of their usefulness to human beings and independently of our judgments about their value.

This openness is especially important with respect to the value of anthromes. Humans have been modifying ecosystems since the discovery of fire, but until recently they were thought of as parts of ecosystems that were largely determined by other factors such as climate, geology, and terrain. Our influence upon the environment, however, has become so pervasive that it is reasonable to think that this relationship has changed, and that human activity itself has become a significant factor in determining the patterns that define an ecosystem. This argument follows the same reasoning for concluding that the current geological period should no longer be called the Holocene. It should instead be named the Anthropocene because of the radical ways in which humans have shaped the climate and environment. Accordingly, biomes that have been permanently modified by human activity may be called anthromes.

This understanding of the significant effects that human activity has on the environment was clearly stated by Rachel Carson in her hugely influential work, *Silent Spring*. Her main concern in this work was the damage that pesticides, especially DDT, were having on the environment. Noting that for most of the history of the earth vegetation and animal life have been determined by the environment, she goes on to claim that "only within the moment of time represented by the present century has one species-man-acquired significant power to alter the nature of his world" (Carson, 2002). Although Carson was concerned about human destruction of the environment, the environmentalist Bill McKibben has written generally about the way humans have left their imprint over the entire globe. He writes about this influence as the end of nature by which he means that nature and its processes no longer exist and function independently of human influence. The clearest example is the way in which human pollution has changed the atmosphere and as a result changed the weather. "By changing the weather," McKibben argues, "we make every spot on earth man-made and artificial. We have deprived nature of its independence, and that is fatal to its meaning" (McKibben, 1989). That, in other words, spells the end of nature.

From this more general perspective, Erle C. Ellis and Navin Ramankutty have argued for the existence of various anthromes, anthropogenic biomes, that range from the most densely populated urban areas to the least populated wilderness areas. They distinguish six types. *Dense settlements* are areas that have high populations with substantial urban areas. *Villages* are areas with dense agricultural settlements. *Croplands* include areas where annual crops are grown along with other land uses. *Rangelands* are characterized by livestock grazing with minimal crops and forests and may have varying levels of human populations. *Forested* areas are those biomes that have forests with human populations and agriculture, but where these populations are minor or inconsequential. Finally, *wildlands* are those biomes without human populations. The shift in perspective that they argue for is a shift from a model of the world as "natural ecosystems with humans disturbing them" to one of "human systems, with natural ecosystems embedded within them" (Ellis and Ramankutty, 2008). This shift, they believe, is necessary for the sustainable management of the biosphere in

the future. It is here that the role of ethics in valuing anthromes will be crucial because ethical principles will be needed to provide guidelines for the decision making involved in this management. Let's look now at three different frameworks for valuing anthromes.

Ethical Frameworks for Valuing Anthromes

The first framework that is useful for valuing anthromes was developed by Richard Shweder and his colleagues (Shweder et al., 1997). It is an ethical framework that psychologists have used to characterize moral reasoning and decision making across cultures. It identifies three distinct ethics that have cross cultural significance: the ethics of autonomy, the ethics of community, and the ethics of divinity. The perspective of this framework may be called *descriptive moral psychology*. It captures the way in which people characterize and understand ethical decision making. The second framework captures three types of moral theories philosophers have used to describe moral judgments about right and wrong and good and bad. They have traditionally distinguished between deontological ethics, consequentialist ethics, and virtue ethics. The perspective of this framework is *traditional ethical theory*. The third framework was developed by Andrew Dobson to describe ways in which environmental writers have approached issues related to environmental sustainability (Dobson, 1998). He distinguishes three different conceptions of environmental sustainability largely understood in terms of what aspects of the environment are most valued and need to be sustained. According to the first conception, environmental sustainability means maintaining critical natural capital because of its value for human welfare. According to the second, sustainability means maintaining natural capital because of its value for human welfare, but it also includes the preservation of irreplaceable natural resources for their intrinsic value. According to the third, sustainability is mainly about preserving nature because it is valuable for its own sake and should be preserved independently of whatever value it may have for human welfare. This framework is described as *conceptions of environmental sustainability*.

These three frameworks are not mutually exclusive. They are best thought of as three different lenses through which we can consider the environment and make judgments about the value different aspects of the environment have. Someone whose ethical perspective draws on an ethics of community may also make judgments that are justified by reasoning that appeals to a deontological ethics and that illustrates a conception of environment sustainability favoring the preservation of natural resources for human welfare. For example, this person may see the natural environment as valuable in the context of family and the local community and justify preserving green spaces within the city by appeal to our duties to provide our children with opportunities to learn about nature. Let's examine the details of each of these different ethical frameworks to understand them better and how they may be used in valuing anthromes.

Ethical Conceptions in Descriptive Moral Psychology

Richard Shweder and his colleagues developed their taxonomy of ethical conceptions by analyzing the ethical discourse of residents of Bhubaneswar, Orissa, India using structured interviews regarding incidents of ethical transgressions (Shweder et al., 1997). We categorize this type of analysis as descriptive psychology since it is an attempt to determine and describe what normative concepts members of a community employed in understanding decision making regarding actions with potential benefits and harms. Analysis of these interviews yielded a list of 16 moral themes which were then organized into three different ethics based on conceptually linked themes: the ethics of autonomy, the ethics of community, and the ethics of divinity.

The normative concepts of the ethics of autonomy are harm, rights, and justice. This understanding of ethics assumes that persons in society are independent from one another and pursue their own interests first and the interests of others or of the society second. Right and wrong are found in the benefits and harms that someone's actions may cause to other agents, and violations of rights are censured. As a result, individual freedom and human choice are central to this conception of ethics.

The normative concepts of the ethics of community are duty and obligation. These are established by a person's role in the family, community, or society. Rather than seeing society as an aggregate of individuals, this conception of ethics situates persons within larger interdependent groups such as family, the local community, and society. Their roles in these groups are frequently established by hierarchies. In the family, for example, the parents have duties to protect and defend their children based on their superior position, and the children have duties to respect and obey their parents based on their inferior position. This conception does not deny the existence of individual desires and interests, but it subordinates these to the good of the larger groups persons are dependent on. Each person is important, but the preservation of family groups, social relationships, and the community is more so.

The normative concepts of an ethics of divinity arise from a sacred or natural order that is established by divine ordinance. The sacred value of persons is derived from their relationship to and participation within this divine order. Duties and obligations toward others are ultimately based on this larger sacred order which is a focus of ultimate concern. Since human action is understood in the context of a sacred order, one that is established by religious tradition, wrong doing is frequently characterized as a sin that degrades the sacredness of a person and of the natural order. Within this conception moral violations of religious obligation established by the natural law lead to impurity and pollution that need to be remedied by sacrifice, punishment, or forgiveness. Each person is important as are human communities, but within this ethics of divinity human beings have a supernatural vocation (Shweder et al., 1997).

Part of the rationale for applying this ethical framework to valuing anthromes is its use in psychological literature related to moral development and moral emotions. For example, Lene Jensen uses the three ethics of this framework to broaden our

understanding of moral development that may be applied across cultures (Jensen, 2011). Paul Rozin and his colleagues use this framework to study and map the moral emotions of contempt, anger, and disgust (Rozin et al., 1999). The other part of the rationale for using this ethical framework is that contemporary philosophers present theories of justice that employ similar categories. Political philosophers who write in the tradition of liberalism typically presuppose a conception of society as an aggregate of individuals in pursuit of various conceptions of the good, which aligns with the ethics of autonomy. By contrast, philosophers who are representative of the communitarianism movement in political thought have emphasized the role of society in determining the nature of a person, and their thought seems to fit within normative concepts of the ethics of community. Other political philosophers draw on a natural law theory that is rooted in the thought of Thomas Aquinas, which would clearly fall within the ethics of divinity.

This framework from descriptive moral psychology creates a suitable perspective for valuing anthromes for at least three reasons. First, these different concepts are drawn from actual conversations about ethical decision making, so they are likely to be realistic ways in which people assign value to human anthromes and include them in their ethical deliberation. Second, they are cross cultural concepts, which is essential for having universal ways of valuing anthromes. Finally, though they describe norms that are already in place among various groups of people, they also roughly correspond to norms that have been carefully established as part of philosophical and political discussions of value.

Ethical Norms of Traditional Moral Theories

The second framework that may be used for valuing anthromes is based on three traditional moral theories. Moral philosophers commonly distinguish between deontological ethics, consequentialist ethics, and virtue ethics. A deontological ethics presents moral agents with fundamental moral rules and obligations for everyone to follow. These rules may be based on conventions which determine that certain actions like breaking promises and injuring innocent people are *prima facie* wrong while others like telling the truth are right. Sometimes the moral rules at the heart of a deontological ethics can be traced back to religious scripture which includes rules like golden rule or the 10 commandments. In the philosophical literature, the German philosopher Immanuel Kant famously proposed a categorical imperative or principle for all rational agents that they should act in ways that their actions could be a universal law for all agents (Kant, 1994). The view that there simply are some fundamental human rights with the understanding that these rights shall not be violated would also be an example of deontological ethics.

A consequentialist ethic bases right and wrong on the good or bad consequences that actions produce. The British philosopher John Stuart Mill's utilitarianism is a good example of a consequentialist ethics. According to Mill, actions that produce the greatest happiness overall are right and actions that lead to unhappiness are wrong. By happiness Mill understands pleasure and the absence of pain and by unhappiness pain and the absence of pleasure (Mill, 2001). Other utilitarians understand happiness in terms of individual satisfactions. For many consequentialist theories of ethics, the nature of the good is defined and then right and wrong are determined by what actions produce this good. This theory of ethics contrasts sharply with a deontological ethics in which what is right is determined independently of what is good or of the consequences of actions. By separating these two, actions that are right in a deontological ethics may lead to consequences that may not be deemed good insofar as the good is identified with human happiness. Since consequentialists define what is right in terms of what produces the good, the same problem does not arise for them.

A virtue ethics bases right and wrong on those actions that contribute to the development of specific virtues and vices as states of a person's character. Most virtue ethics trace their roots back to Aristotle. He defined virtues such as courage and justice as states of character created by actions that are a mean between excess and deficiency with respect to an identifiable moral context. Courageous actions, for example, are a mean between actions that exhibit an excess or a deficiency of fear. In his view the practice of virtues throughout a lifetime would lead to a person's happiness and to the well-being of society (Aristotle, 2000). So the consequences of actions were certainly part of his thinking about ethics. Identifying human virtues, however, and examining how they are cultivated were of central concern. Traditional virtues in Greek society were courage, temperance, justice, and practical wisdom. Later in Medieval philosophy under the influence of Christianity the theological virtues of faith, hope, and love were added to this list. In contemporary philosophy benevolence, charity, generosity, loyalty, and tolerance can be included among the virtues.

These three traditional ethical theories are not exhaustive of possible ethical theories that might be used to value anthromes but they do provide a good starting point. From each of these different theories it is easy to imagine ethical norms and values that can be applied to the human activities that shape biomes around the globe. From the deontological perspective, it would follow that human beings establish rules for human development that can be made into universal laws which include both the way this development affects human beings and the way it affects all the living beings and systems within a biome. From the consequentialist perspective, it would follow that human beings must make decisions by considering as thoroughly and extensively as possible the possible consequences of different actions and policies for humans and other sentient beings in the natural environment. Virtue ethics implies that we should cultivate what might be called environmental virtues that encourage us to be good citizens of the anthromes in which we live. To paraphrase Aldo Leopold, we might think of these virtues as appropriate to humans who no longer think of themselves as conquerors of the land but as plain members and biotic citizens of it.

Ethical Conceptions of Environmental Sustainability

The third framework for examining the ways in which we can value anthromes approaches environmental value from the perspective of environmental sustainability. This framework was developed by Andrew Dobson to classify ways in which thinkers on

environmental sustainability answer questions about what needs to be sustained and why. In contrast to the conception of sustainable development, which has been the focus of much discussion, Dobson makes the concept of environmental sustainability central to his discussion. When we realize that we depend on natural capital to last into the future that cannot be completely or partially replaced by human made capital we have introduced the notion of environmental sustainability. For any theory of sustainability to be about environmental sustainability, he observes, it is essential “that it argue for the sustaining into the future of some aspect of the natural environment” (Dobson, 1998). Dobson distinguishes three conceptions of environmental sustainability. First is a conception that emphasizes the preservation of natural resources for human welfare. Second is a conception that recognizes the preservation of natural resources for both human welfare and non-human welfare, especially those that are irreplaceable. This conception also includes considerations about our duties toward nature independent of human beings. Third is a conception that emphasizes the preservation of nature simply for its own sake rather than for its value for human purposes.

According to the first, what needs to be sustained is critical natural capital. Critical natural capital includes those natural resources and systems that are essential for human survival. It would include water, land, and energy resources, but would also include biological systems and processes. Dobson is happy to include these larger systems within the description while acknowledging that some may think of critical natural capital mainly at a local level as referring to arable land and clean water sources for agriculture. Within this conception of environmental sustainability, the overriding reason for sustaining critical natural capital is to promote human welfare. Since human beings need natural resources in order to live, it is essential that this critical natural capital be sustained indefinitely. Dobson argues that most of the discussions of sustainable development understand and value natural capital in economic terms and argue for its preservation from the anthropocentric perspective that informs this first conception of environmental sustainability. When the question turns to how this sustainability is to be achieved, proponents of this first conception argue for renewing the natural resources that can be renewed, substituting for those which may be endangered or which may simply be running out, and protecting those resources for which there may not be acceptable substitutions. This conception of sustainability emphasizes finding suitable substitutions for critical natural capital that we can depend on in the future. If we could always find such substitutions, then we would not even be looking at a theory of environmental sustainability. But as long as there are some natural resources we can't replace with man-made substitutions, and if we need these resources into the future, Dobson argues, “we are in the presence of a theory of environmental sustainability” (Dobson, 1998). So the first conception of environmental sustainability involves sustaining critical natural capital because it is necessary for human welfare. We sustain critical natural capital by renewing it if possible, substituting human made capital to the extent this is feasible, and protecting the rest.

The second concept of environmental sustainability shifts what needs to be sustained from critical natural capital to resources and other aspects of nature that are being irreversibly lost. The paradigm case of such change is the loss of biodiversity that occurs with the extinction of species. This irreversible natural change can be significant because it means the loss of something that is critical for human welfare, such as the loss of petroleum reserves. But it can also be significant because it means the loss of species that have intrinsic value independent of any use value for human beings. In cases for which irreversible losses to nature have no clear bearing on human welfare, our reasons for avoiding them will gravitate toward arguments that relate to our duties toward nature as such. In Dobson's view this may also involve a sort of weighing of consequences that is common to utilitarian reasoning because we cannot avoid all irreversible losses. As a result, “the benefits from some losses need to be weighed against the gains that might result from the loss.” What is important in this conception is that “the notion of irreversibility needs to be taken into account when calculations of this sort are made” (Dobson, 1998). Since the losses of irreversible nature obviously cannot be renewed the only options for how to handle them are either substitution with something human made that provides the same benefits for human welfare or protection. Protection and preservation, for example, are essential ways to sustain biodiversity and prevent the further extinction of species that are being lost as a result of human development and interference with natural habitats.

The third conception emphasizes the importance of protecting and preserving natural value as such because we have duties to other species and nature or because we believe that they have intrinsic value that must be respected. From this perspective there may be little if any concern about ways in which we can or should develop human-made capital to replace critical natural capital. Of the three conceptions of environmental sustainability, this conception is clearly what we might call the greenest. In literature related to sustainability, it is a version of what Wilfred Beckerman calls “strong sustainability” because it can be understood as the requirement to preserve nature as it is now for future generations for its own sake (Beckerman, 1999). Weaker versions of sustainability advocate preserving nature for the sake of human beings.

At the same time that this framework captures different conceptions of sustainability that have been presented by philosophers and environmental activists over the past few years, it also takes for granted the idea of nature as something separate from human influence. This is especially noticeable in the third conception which argues for sustaining nature as it is now for future generations. Since human activity and development now have a global influence, it is no longer possible to think about a pristine nature that can be preserved and protected from future human influence. It does not follow, however, that we cannot value and protect the beauty of natural spaces for themselves. Consequently, each of these conceptions of sustainability has important implications for valuing anthromes.

The first conception of sustainability emphasizes the importance of conserving, protecting, and preserving those natural resources that essential for human survival and further emphasizes the search for alternative resources that have less environmental impact. The second conception of sustainability pays particular attention to those resources that are irreplaceable, such as petroleum reserves. It also recognizes the intrinsic value that other living beings have and the importance of our taking responsibility for managing and caring for them. This might include a more sustainable agriculture that relies less on chemical fertilizers that are toxic to the land and water as well as kinder provisions for raising animals that are needed for food. The third conception of sustainability

makes room for the recognition that nature in whatever form, from less populated wild areas to urban green spaces has value for human life and intrinsic value. Thinking about any sort of urban or land management benefits from recognizing the instrumental and the intrinsic value of all those aspects of the natural environment that we interact with.

Conclusion

As human development and industrial activity continue to have a significant influence in shaping the ecosystems within which we live, it is especially important to broaden the scope of our ethical thinking and deliberation to include all aspects of the natural environment. There are many goals that have vied for pride of place in the writings of philosophers and environmentalists not the least of which is sustainability. Certainly, valuing the various anthromes that cover the globe must make this one of the important priorities. Others include protecting biodiversity and reducing the current high rate of species extinctions. From a human perspective it is important to preserve green spaces and relatively wild environments for their beauty and capacity to vivify the human spirit. At the same time, it is equally important to create and preserve the sort of social, educational, and economic opportunities that are essential for human happiness. Although the ethical frameworks presented here are not exhaustive, they give a significant variety of perspectives for valuing anthromes that enable us to achieve a sustainable balance between human needs and interests on the one hand and what is needed for other living beings and living systems to thrive on the other. Every anthrome like any other biome is a home to all the living beings that inhabit it. Just as any home has rules to protect the interests of everyone who resides there, we need to draw on the established ethical frameworks that we have at our disposal to guide our behavior toward all members of our anthromes.

Abstract

This article tracks the metamorphosis of the idea of wilderness in light of major shifts in thought on conservation strategies and attendant politics. The article opens with a long history of the concept, noting its debts to religious discourses and sublime aesthetics that underwrite ambivalent notions of wilderness as being sacred and terrible, all of which ground notions of wilderness as being necessarily distinct and separate from “civilized” human beings (Garrard, 2012). Next is an overview of geographical associations with the term, such as correlations between wild and west, between wilderness and empty spaces, between uncharted ground and colonial enterprise or even imperializing plunder (Cronon, 1995; Garrard, 2012; Guha, 1998; Miller, 2018; Plumwood, 1998). In so doing, this article’s trajectory sets out to explore wilderness in its seemingly innocent registers that align freedom and power with so-called pristine or pure landscapes. In addition, it details more recent thinking that positions wilderness as a politically- and historically-fraught concept. In terms of the latter understanding, wilderness concepts emphasize polar differences between humanity and nature that ideologically support the spread of an homogenizing, imperializing cultural logic, ultimately spurring human displacements while harming interrelated, interdependent non-human lifeforms and biodiversity in the process (Denevan, 2011). In conclusion the essay introduces nascent branches of alternative wilderness thinking relative to conservation efforts that pertain to both humans and nonhumans and thus transcend typical wilderness dualisms that growing numbers of researchers find to be deeply problematic and detrimental to environmental conservation aims.

Introduction

Where does the wilderness begin or end? How do we know the wild? Answers to such questions tend to be found at the limit of changing definitions of the human if not human culture. For example, a recently published installment of *Nature’s* correspondence section makes clear how ideas of the human, and in turn, how ideas about the inhuman or abhuman shape wilderness thinking as well as wilderness conservation efforts and research. Life sciences specialists joined with forestry researchers to urge readers of *Nature* to once and for all “[a]gree on [the] meaning of wilderness ... [as] a map of valued natural regions [that] should include all wild lands generally judged to be important ... Otherwise, policymakers might wrongly infer that omitted areas are tainted by human presence and no longer worth protecting” (Sheil et al., 2019, 429).

If humans are present, it is assumed that wilderness is not, and thus the impetus for protecting valued wild lands is precisely because they are not (yet) “tainted by human presence” (Sheil et al., 2019, 429). Such urgent pleas for guarding wild spaces by deeming them prized wilderness areas begs the following question: from what do these wild regions need protecting? It might be easy to suggest humanity as the logical and commonplace response, but so-called wild lands might also need protecting from being deemed untouched wilderness, since to certain modern developers wilderness lands are tantamount to storehouses of untapped resources (Sayles, 2015). Ironically perhaps, and as the above example from *Nature* shows, concepts of wilderness long associated with places and states of wild, uncontaminated, or protected nature continue to stage important debates about human culture largely because wilderness concepts so often assume a stark separation between the natural and the cultural (Garrard, 2012). As Timothy Clark puts it in *Nature, Post Nature* “there is nature understood as the other of culture, that which arises of itself without human agency. It may be revered as wilderness or pristine animality, or feared as the bestial and cruelly inhuman. Looser variants of this sense use nature to name the biosphere, or, more casually, a certain idea of the rural as opposed to the urban” (Clark, 2013, 75–6).

While a general consensus might suppose that to study the wilderness is to study biomes remote from humankind, in fact wilderness studies must to some extent examine subsets of the world’s anthromes (Ellis and Ramankutty, 2008; Martin et al., 2014). That is, wilderness researchers necessarily investigate select portions of the world’s anthropogenic, human-influenced biomes, since with anthropogenic “climate change and distribution of pollutants, there is no place on Earth that has not been altered by humans” (Williams et al., 2015, 197; Lieberman et al., 2018). The question then becomes one of determining the extent of human modification to various regions in order to designate areas on the globe as wilderness or wildlands. For example, Conservation International prioritizes and puts particular emphasis on high biodiversity wilderness. According to their agreed upon definitions and markers, high biodiversity wilderness areas must hold a vast majority of their endemic species and be comprised

of at least 70% of their natural habitats (Newbold et al., 2016). Yet to fail to acknowledge the wide array of case-by-case definitions of wilderness, “natural,” wild, or undisturbed lands, or to ignore the sociocultural spectrum of debates framing concepts of wilderness risks gross misunderstandings, as discussed in the following article. Failing to account for shifting definitions of wilderness and the attendant sociocultural problems sparked by narrow wilderness thinking also risks missing altogether the degree to which human definitions of and assumptions about nature inform the various anthromes (wild or not) humanity produces today, not to mention how these divergent wilderness definitions and debates direct conservation policy or any given human value system driving environmental policies.

The following article tracks the metamorphosis of the idea of wilderness, particularly in light of major shifts in thought pertaining to how wilderness environments and wild ecological systems are imagined, or in other words, in light of what could be called the changing terrain of environmental imagination as it relates to wilderness thinking (Purdy, 2015). The article opens with a long history of the concept, noting its debts to religious discourses and sublime aesthetics that underwrite ambivalent notions of wilderness as being sacred and terrible, all of which ground notions of wilderness as being necessarily distinct and separate from “civilized” human beings (Garrard, 2012). Next is an overview of geographical associations with the term, such as correlations between wild and west, between wilderness and empty spaces, between uncharted ground and colonial enterprise or even imperializing plunder (Cronon, 1995; Garrard, 2012; Guha, 1998; Miller, 2018; Plumwood, 1998). In so doing, this article’s trajectory sets out to explore wilderness in its seemingly innocent registers that align freedom and power with so-called pristine or pure landscapes. In addition, it details more recent thinking that positions wilderness as a politically- and historically-fraught concept. In terms of the latter understanding, wilderness concepts emphasize polar differences between humanity and nature that ideologically support the spread of an homogenizing, imperializing cultural logic, ultimately spurring human displacements while harming interrelated, interdependent non-human lifeforms and biodiversity in the process (Denevan, 2011). In conclusion the essay introduces nascent branches of alternative wilderness thinking (Miller, 2018). Such revisionary, non-dichotomous wilderness concepts attempt to afford room for multicultural valuations of wild spaces as well as non-urbanized notions of freedom and liberty.

Blunt Wilderness Binaries

The main trouble with wilderness thinking springs from problems created by its grounding dualisms, or in other words, its blunt and crude binary logics. With its all too easy either-or options, neat this-or-that distinctions, wilderness concepts risk clouding relations and feedback loops existing between and across human and natural systems—relations occurring even in spaces we might call wild (Lieberman et al., 2018). Take for example Thoreau’s famed and paradigmatic expression of the wilderness concept. Thoreau’s grounding assumptions sever the freedoms, agencies, or powers of natural systems from the liberties, license, and rights of humanity’s cultural systems: “I wish to speak a word for Nature, for absolute freedom and wildness, as contrasted with a freedom and culture merely civil” (Thoreau, 1862, 657). The stark contrast between the capitalized, idealized, and universalized version of nature (or ecological communities) that Thoreau aims to speak for, and the relatively smaller, less significant realm of human agency and actions—imagined here as “merely civil”—suggests that human choices, cultures, and histories matter less than the actions and operations of a seemingly omnipotent natural world. Then the depiction of “Nature” as an absolute universal further muddies the waters by making it seem as if ecological systems are timeless and less subject to history, change, or evolution than human systems. In these aspects, Thoreau’s dichotomous wilderness thinking downplays the powerful role that human beings play in any extant natural system’s past, present, or future.

Such dualist misunderstandings of wilderness would later be repatterned, enshrined into law, in effect granting this spurious logic greater currency and staying power by being endorsed by the U.S. federal government and others in following. For instance, in the U.S. the 1964 Wilderness Act (16 U.S.C. 1131–1136) established a preservation system to maintain the “wilderness character” of federally designated areas, offering a definition of wilderness hewing close to Thoreau’s 19th-century account. The document assumes human life to be antithetical to wilderness. Human and natural agencies are not represented as overlapping, interrelated, entangled, or in terms of feedback loops. Rather “earth and its community of life” excludes human beings as well as “human habitation” (Wilderness Act, 1964, 2).

Federally protected wilderness areas welcome humanity only as visitors or researchers, foreclosing the possibility of indigenous human cultures being able to live in these lands regardless of extensive historical, cultural, and ancestral precedents. While it might be tempting to grant that the Wilderness Act does open a backdoor to humanity by allowing intermittent access, its language clearly states that only certain kinds of cultural activities are welcome there, including “opportunities for solitude or primitive and unconfined type of recreation” or the study of “features of scientific, educational, scenic, or historical value” (Wilderness Act, 1964, 2). The dualist language of the law defined wilderness as necessarily separate from everyday human culture or existence, opening protected lands to those solitary itineraries able to afford the occasional leisurely visit, or to those supported by distant if not distinguished research agencies and institutions, while effectively writing out endemic human cultures with long ties to and crucial relationships with their surrounding ecosystems (Dear and Myers Jr., 2005; Garrard, 2012; Guha, 1998; Harmon, 1998; Miller, 2018).

Influential critiques of wilderness discourse find its abiding logic troublesome not only when “anthropocentric-biocentric distinctions [are] accepted as axiomatic” but also when “it quietly expresses and reproduces the very values its devotees seek to reject” (Guha, 1998, 233; Cronon, 1995, 80). William Cronon’s landmark work *The Trouble with Wilderness* grapples with what he calls the “central paradox” of wilderness thinking. Cronon stresses how “wilderness embodies a dualistic vision in which the

human is entirely outside the natural. If we allow ourselves to believe that nature, to be true, must also be wild, then our very presence in nature represents its fall" (Cronon, 1995, 80–81). He goes on to argue that if "this is so—if by definition wilderness leaves no place for human beings, save perhaps as contemplative sojourners enjoying their leisurely reverie in God's natural cathedral—then also by definition it can offer no solution to the environmental and other problems that confront us. ... Worse: to the extent that we live in an urban-industrial civilization but at the same time pretend to ourselves that our real home is in the wilderness, to just that extent we give ourselves permission to evade responsibility for the lives we actually lead. We inhabit civilization while holding some part of ourselves—what we imagine to be the most precious part—aloof from its entanglements" (Cronon, 1995, 81).

For Cronon, at the heart of wilderness thinking is the misleading idea of escape: escape from history and escape from responsibility. Under the rubric of conventional wilderness wisdom, humanity is left off the hook in relation to caring for, managing, or conserving any and all ecological systems that necessarily support human life and culture. Of course, it is important to bear in mind that Cronon emphasizes that his critique is not mounted against those working to protect "wild nature per se, or even to set aside large tracts of wild land" (Cronon, 1995, 81). In contrast, his aim is to expose "specific habits of thinking" spurred by "this complex cultural construction called wilderness" (Cronon, 1995, 81). In Cronon's analysis, the concept of wilderness, be it mentioned in professionally published discourse or common conversation, cannot avoid triggering problematic habits of thinking that ultimately work to undermine anyone's attempts to protect the planet's least human-influenced areas.

Wilderness Roots and Regionalisms

According to Greg Garrard's influential study of the idea of wilderness, such problematic patterns of thought have their roots in cultural geography and religious thought. Garrard's account of wilderness "as the most potent construction of nature available to New World environmentalism," exposes how the concept enjoys a sublime, "almost sacramental value" because of the pivotal role the idea held in relation to "the settler experience in the New Worlds—particularly the United States, Canada, and Australia—with their apparently untamed landscapes and the sharp distinction between forces of nature and culture" (Garrard, 2012, 67). Garrard's research into the sociocultural underpinnings of wilderness logics that assume a fundamental disconnect between ecology and humanity as well as between nature and culture charts how these overlapping dichotomies arise from "a set of distinctions ... based upon a mainly agricultural economy" (Garrard, 2012, 67). Emerging farming communities began to frame notions of home against wilderness and nature due to assumptions that the labors of the farmer are tantamount to a "struggle against nature" equated to Judeo-Christian notions of the curse of toil. The Judeo-Christian model informing most iterations of wilderness concepts in the West "combines connotations of trial and danger with freedom, redemption and purity, meanings that, in varying degrees it still has" (Garrard, 2012, 68).

Thoreau's body of work sheds further light on how the freedom attributed to wilderness not only supported associations between the wild, wilderness, and the West, but also helped to legitimate western expansionism under the banner of Manifest Destiny in United States, a doctrine typified by Jackson Turner's "Frontier Thesis" (Cronon, 1995). In his influential essay penned for the *Atlantic Monthly*, "Walking," Thoreau puts into words and thus helps cement conceptual links between uncharted, "uncivilized" wild spaces with opportunities for individual growth and individual rites of passage that appear to be inseparable from new opportunities to tap untouched natural resources and to access assumedly uninhabited spaces. "When I go out of the house for a walk," Thoreau writes, "uncertain as yet whither I will bend my steps ... I find, strange and whimsical as it may seem, that I finally and inevitably settle southwest, toward some particular wood or meadow or deserted pasture or hill in that direction. My needle is slow to settle, varies a few degrees, and does not always point due southwest, it is true, and it has good authority for this variation, but it always settles between west and south-southwest. The future lies that way to me, and the earth seems more unexhausted and richer on that side" (Thoreau, 1862, 662).

Thoreau's 19th-century coupling of wilderness and a kind of settler colonial logic in line with the doctrine of Manifest Destiny in the United States endures in current wilderness conservation research published across the North America, Europe, and in other regions with large Anglophone populations such as Australia. For example, a highly cited publication with a correspondingly high impact factor holds a title that bears witness to deep and lasting associations between wilderness concepts, colonial and frontier logics, and histories of western expansionism: "The last frontiers of wilderness: Tracking loss of intact forest landscapes from 2000 to 2013" (Potapov et al., 2017, 1). In similar spirit but stated in even more direct terms, another influential study makes synonym out of "wilderness or frontier areas," with wilderness and frontier becoming interchangeable (Laurance et al., 2014, 229). Confirming Cronon's analyses, regardless of whether or not researchers intend to repattern longstanding linkages between nationalist colonial agendas and wilderness concepts, publications on wilderness conservation run the risk of reactivating enduring links not only between wilderness thinking, colonial conquest, and a sense of entitled access to "undeveloped" lands, but also regardless of any existence therein of ancestral human communities. Researchers thus would do well to acknowledge these historical and ideological entanglements.

By explicitly acknowledging the colonial and imperial associations held between "uncharted" or "untouched" wilds and fantasies of a winner-take-all frontier ethos, researchers can begin to better study and more deeply understand the disconnects at play in Thoreau's logic which remain powerfully active today (Sayles, 2015). Thoreau's reverence for and questing after an earthen terrain that "seems more unexhausted and richer" neglects and downgrades the comparatively impoverished, spoilt, and unpromising

grounds that in fact supported his everyday existence, ignores his own part to play in any “spoiling” process, imagines away human livelihoods other than his own, and falsely presumes a seemingly endless reserve of future wild spaces to escape to, or to at least access if not flat out exploit.

Wilderness Conservation and Environmental Colonialism

Postcolonial critiques of wilderness are often at pains to point out how Western philosophy’s sacralization of sublime wilds and pure nature masquerades as valuing nature above all else, but in truth advances dominant regional, national, or imperial goals (Guha, 1998). Environmental colonialism describes the process of forcing a dominant nation, group, or region’s ecological thought and conservation priorities onto other places and peoples, assuming a one-size-fits all approach that routinely fails to respect endemic communities of both human and nonhuman kinds for what they are and for how they work (Guha, 1998). Well known examples include how the United States National Park system forcibly removed indigenous populations out of their ancestral homelands in the name of establishing and protecting the nation’s greatest natural treasures (Guha, 1998; Garrard, 2012; Miller, 2018). Without considering how this process forever changed those environments and their endemic human cultures, this practice has been adopted and repatterned in other countries. Take for example India, where preserves were established to protect animals highly valued by western aesthetics and institutions (Tigers) at the cost of dislocating the area’s often impoverished human residents, in turn causing lasting damaging modifications and disturbances to the newly “protected” area (Guha, 1998). As Cronon reminds us, the “removal of [indigenous communities] to create an “uninhabited wilderness”—uninhabited as never before in the human history of the place—reminds us just how invented, just how constructed, the American wilderness really is. To return to my opening argument: there is nothing natural about the concept of wilderness” (Cronon, 1995, 79).

The faulty dualistic thinking so fundamental to most wilderness constructions proves damning once again, setting up biodiversity conservation as mutually exclusive from supporting human cultures when the opposite has often been the case (Porter-Bolland et al., 2012; Keeling and Sandlos, 2009). The more diverse human cultures that flourish on earth by divergent means of subsistence opposed to the wasteful conventions characteristic of industrial societies in fact help to support, sustain, and preserve biodiversity, with indigenous communities providing important models for protecting and conserving threatened environments within which they live and which they call home (Guha, 1998; Pearce, 2016; Sayles, 2015).

To better fathom the dynamics of environmental deterioration looming over all spaces of the globe, inclusive of its least human influenced areas, it would be a mistake to bracket off wilderness from its relations to other natural and human systems. Mythologized investments in preserving the planet’s remote and so-called pristine areas—flown under the banner of wilderness conservation—cannot bear real fruit without also investigating leading drivers of ecological degradation, such as excessive, uninhibited consumption and wastefulness that has yet to be counterbalanced by cultural shifts toward an ethic of restraint and self-limitation (Guha, 1998; Denevan, 2011). This would balance out the simplistic thinking behind wilderness logic that would suggest that wilderness politics have nothing to do with questions of social justice or equity (Keeling and Sandlos, 2009; Miller, 2018). But since ecologically draining and damaging patterns of overconsumption predominate in the richest, most industrialized countries, it is imperative that the dualist politics of wilderness conservation not be allowed to mistake all human presences in natural areas as being equal or that social justice issues are unrelated to wilderness issues. The key here is that wilderness conservation proponents need to understand how setting aside protected wilderness areas by dislocating and displacing people living in these areas directly transfers resources away from the poor and into the hands of the rich, exacerbating cycles of entitled overconsumption and weakening communities that do least harm to their surroundings, not to mention playing important roles in their home ecosystems (Guha, 1998; Porter-Bolland et al., 2012; Sayles, 2015).

A more tempered and nuanced understanding of wilderness is necessary, where humanity and wilderness are not necessarily contradictory so that conservation practices can help maintain human communities promoting biodiversity and furthermore so that a larger cross section of human cultures are preserved to help counteract wasteful and damaging models of industrial overconsumption predicated upon unchecked expansionism, an expansionism itself reliant upon encroaching into previously “untouched” or “untapped” lands, resources, and communities (Porter-Bolland et al., 2012; Keeling and Sandlos, 2009).

Marking a move in the right direction, rather than only defining wilderness as antithetical to humanity or human culture, we could follow those researchers and scientists who are beginning to distinguish wilderness not against any monolithic concept of humanity or culture, but by a given community’s relationship with and impact on its home environment. Then, for example, we would know wilderness or wildlands by measuring the “degree to which a place is remote from and undisturbed by the influences of modern technological society” rather than simply and crudely by human presence alone (Pärtel et al., 2017).

NatureCultures and Alternative Wilderness Thinking

Can more nuanced, accurate, and responsible alternative wilderness concepts prevail? Can future adopters of the term shake off the concept’s compromising binary logics and reductive dualisms, perhaps instead reactivating “a more richly researched, more imaginatively inclusive” concept that “understood wilderness as a space of liberation that had to be maintained by caring human hands, a place where identity, landscape, community, and memory defined one another? Such would be a creative definition of wilderness that presupposed occupation and laboring, an idea that would have little to do with the notion of the lone, white, male sojourner

coming face-to-face with a sublimely empty nature while on vacation. It would be an equation of wilderness with freedom, with community, with home" (Miller, 2018, 71). So writes wilderness historian Daegan Miller as he reopens the thorny question of "what is wilderness" (Miller, 2018, 52). In his meticulously researched revisionist history of the Adirondack wilderness, Miller pushes back against dichotomized wilderness thinking. He counters patterns of thought conflating wildlands with mythologies of emptiness that erase human and nonhuman histories, and with them their respective work, their respective disturbances, their respective fullnesses, their respective and sometimes overlapping communities. As Miller notes, the "tragedy of wilderness is that all that howling emptiness that many of us now celebrate obscures all that violent history of emptying" (Miller, 2018, 53).

Miller's alternative wilderness accounts offer lines of analyses that hew closely to Donna Haraway's idea of naturecultures, where rather than being mutually exclusive nature is presumed to entail various cultures comprised of both humans and nonhumans (Haraway, 2003). Miller does not fall prey to reductionist oppositional logic. Instead Miller prescribes an understanding of wilderness predicated upon a complicated relationality emblematic of naturecultures, where what qualifies as wilderness might be a "community of trees" and where "unsettled, or untouched, or unbroken" land "didn't mean that it was empty or unpeopled, or even uncleared—it just meant that the predominant view was of forest" or by extension, of any given type of wilderness (Miller, 2018, 88). He embraces wilderness concepts in light of process thinking, striving to account for particular conjunctions and complicating relations. In Miller's detailed research on specific places and particular peoples, we find wilderness alongside work, wilderness with home, wilderness as communal, wilderness as full. Just as humanity is not treated as a monolith in these particular histories of Adirondack wildlands and their human and nonhuman communities, neither is wilderness or wilderness thinking singular or narrowly defined. Rather than falling back on blunt wilderness binaries that mainly perpetuate and reflect concepts linked to histories of settler colonialism and ecological imperialism damaging to both human and natural systems, wildernesses become something both particular and capacious. "Recognizing difference means that many wilderness travelers thought of the woods not as empty, virginal, and waiting to be penetrated by culture—the definition of wilderness that prevails today—but instead as full: full of sound, full of smell, full of health, full of trees and animals. Full of life" (Miller, 2018, 89).

Abstract

Although our ancestors probably also sensed it, we now know that there is an interconnection between human wellbeing, and the well-being of the anthromes and biomes (A&B) we interact with. Biomes can be thought of as ecological regions characterized by the living things, landforms, and climate in those areas. In addition to the same elements that characterize biomes, anthromes also experience human impact. This interconnection calls for a more interdisciplinary approach to model building and practice in two areas:

First, in addition to traditional biological and geophysical processes, ecological theorists also need to include human cultural, psychological, sociological, and spiritual processes in their model building, in order to investigate, understand, and address the consequences and causes of anthropogenic ecological change (Ellis, 2015).

Second, mental health theorists need to add an ecological perspective to their model building. Since ecological factors influence physical and mental health, professional helpers who serve the mental health needs of individuals and communities need to add an ecological perspective to their practice (Derezotes, 2016).

In this article, an ecobiopsychosocialspiritual (EBPSS) approach to community practice is described, that combines the insights of ecopsychology with social justice values. Then, the reader will be given examples of how to use this EBPSS approach to both understand and transform human interactions with anthromes and biomes.

Introduction

Humanity's advancements in the development of manufacturing, transportation, construction, bio-engineering, energy, and communication technologies continue to outpace the development of conscious and loving relationships with each other, other life forms, and the ecosystems that support all life.

This disparity increasingly intensifies the Global Survival Threats (GSTs) that loom over humanity's future, as well as the future of many other species and the ecosystems that support all life on our planet. These interrelated threats include overpopulation, climate change, preparations for war, and destruction of natural resources (Derezotes, 2005).

Humanity is already experiencing widespread psychological, physical, and social impacts related to GSTs (Doherty and Clayton, 2011). There is evidence that many past societies have disappeared because of local ecological collapse, primarily due to overuse of resources (Moffett, 2018). Today, our individual and collective lack of consciousness about our interconnection with the deteriorating state of our anthromes and biomes has been linked to widespread and increasing depression and anxiety (Macy and Johnstone, 2012) and the distress of "solastalgia" (Albrecht et al., 2007) observed in human populations across the planet. We also know that poor and other minoritized populations tend to experience the greatest impact of ecological change across the globe (Shiva, 2015).

Ecologists and mental health professionals can work together with other disciplines to educate the public about the urgency of ecological GSTs; this chapter is written in the spirit of developing such increasing multidisciplinary cooperation. Because of limited space, this chapter can only be an introduction to this complex and fascinating subject. Some basic concepts, for example, related to

mental health assessment and intervention with clients are offered, but many important details of practice are not included. The phrase “well-being” will be used to include the overall multi-dimensional health of humans and of the A&B we live in.

An Ecobiopsychosocialspiritual Approach to Practice

As the name suggests, the EBPSS approach includes five interrelated dimensions. The “psycho” or psychological dimension is derived from a Greek word for “breath of life” and today is understood to be about the mental construction of a person. “Social” is derived from a Latin word that refers to the relationships between people. “Bio” comes from a Greek word that signifies all life, and “eco” from another Greek word that refers to the connection between life and the environment. Spirituality derives from the Latin word for “breath of life” and today refers to human consciousness and our connection with the Universe. The entire expression suggests that humans are multidimensional beings who are interconnected with the many dimensions of all life and all environments. **Fig. 1** illustrates the interrelatedness of these five dimensions.

A thesis of this chapter is that reconnection with our own inherent multidimensionality, of body, mind, and spirit, can help us also reconnect with other living things and ecosystems, and that such reconnection is a foundation of transformation of human interaction with anthromes and biomes. We cannot connect with nature without connecting also with ourselves, and we cannot connect with ourselves without connecting with nature. The word “healing” is derived from the Latin word for “wholeness”; and the healing of the human race can be conceptualized as the reintegration of all the parts of our EBPSS makeup.

As we heal, and become aware of and express this multidimensionality, our beliefs about and relationship with A&B can also transform. We begin to experience and express what [Wilson \(1986\)](#) called “biophilia,” which is our natural affiliation with all life. There is increasing evidence that spending time in more natural settings, or even interacting with plants and animals, brings measurable physical health benefits to all groups of people; benefits include lowered stress, blood pressure, lowered risk of life-threatening physical and mental illness, and longer life expectancy ([Sheikh, 2019](#)). This biophilia can be experienced and expressed in all five dimensions of development. **Fig. 2** summarizes the discussion of the EBPSS approach.

The Ecological Dimension

In social work and many related disciplines, the terms “ecological” and “environment” have primarily been used to describe human social context, such as family, culture, nationality, and religion ([Derezotes, 2016](#)). In the EBPSS approach, the meaning of the phrase “eco” is expanded to include both human social context as well as the context of urban, village, rangeland, cropland, and other anthromes as well as forest, desert, wetland, tundra, and other biomes ([Wildlife Trusts, 2019](#)).

Humanity is living increasingly separated from the ecosystems that support our lives. A recent study in the United Kingdom for example, revealed that 7 out of 10 people admitted being out of touch with nature; even people living in more rural areas spend increasing time in front of screens, and relatively less time outdoors, than previous generations ([Orr, 2017](#)).

Despite this widespread retreat from nature, human well-being is nevertheless connected with environment. The local environment can strongly influence religious, political, and cultural beliefs and behaviors. Many people have “sacred landscapes,” such as a particular mountain lake, canyon grove, or ocean beach that are especially meaningful to them. A person’s sense of whether she can make a difference in the overall health of his environment is related to their overall well-being, and could be expressed, for example, by her willingness to lobby to have their local or regional government consider A&B in community activities and planning.

The healing of our ecological dimension begins when individuals and communities recognize our interconnectedness with our local and global A&B.

Fig. 1 Interrelated developmental dimensions of individual and collective human well-being.

Dimensions	Theoretical approaches	Central Themes	Examples of evidence of Biophilia
Eco-logical	Community mental/physical health	The community includes not only other humans, but also other life and our ecosystems	Inclusion of A&B in community activities and planning
Bio-logical	Reconnecting with our bodies	Physical health is connected with the health of all life and ecosystem health	Correlations between human well-being and well-being of A&B
Psycho-logical	Eco-Psychology	Mental health is linked with stewardship of other people, other life, and the environment	Beliefs and behaviors that demonstrate commitment to and stewardship of A&B
Socia-logical	Social Justice Perspective	Human well-being is connected with social justice for not only	Beliefs and behaviors that demonstrate commitment
		all humans but also all life and the ecosystems that support us	to social justice of human interaction with A&B
Spiritual	World's wisdom traditions	Development of consciousness (reverent awareness) of human connection with the universe	Beliefs, rituals, and activism that develop and deepen such consciousness

Fig. 2 Constructing an ecobiopsychosocialspiritual (EBPPS) approach.

The Biological Dimension

Over generations, many of us have gradually forgotten that we are animals. In many societies, people tend to believe that humans are the most important species, and that we are the only living things with consciousness, emotions, culture, and morals. The evidence suggests otherwise ([Hogenboom, 2015](#)).

However, we not only increasingly live in separation from other living things, but also live in increasing separation from our own bodies. In fact, most people, especially those of us living in more affluent and “civilized” societies, live in our heads. What does that mean? When I live in my head, most of my awareness is focused on my thoughts, and relatively little awareness is focused on the rest of my body below my neck. I might not, for example, be aware of when my body is hungry or full, needs exercise, or needs rest.

Healing the biological dimension means in part to become reacquainted with the aliveness in my own body, so I can relate to the aliveness all around me as well. That aliveness may include all the sensations, emotions, and energy I may notice in my body from time to time.

The Psychological Dimension

“Ecopsychology explores humans’ psychological interdependence with the rest of nature and the implications for identity, health and well-being” ([Society for Environmental Population and Conservation Psychology, 2014](#)). Ecopsychology has become increasingly recognized and now is represented as Division 34 in the American Psychological Association.

Ecopsychology is an emerging field that is informed by many multidisciplinary and multicultural sources, including Sustainability, Deep ecology, the Green Movement, Biophilia, Shamanism, Transpersonal anthropology, Ecospirituality, Transpersonal ecology, Ecofeminism, Economics [Schroll \(1994\)](#). This ecological perspective has also been recognized in social work and other related disciplines ([Derezotes, 2016](#)).

An important implication of Ecopsychology is the idea that a “mentally healthy” individual, family, organization, or community is connected with and acts as a good steward of local A&B. Conversely, a person may suffer mental health symptoms when she is not aware of her connection with the environment. The [World Health Organization \(2018\)](#) has for many years identified depression and other mental health disorders as among the most serious and widespread global health problems, rooted at least in part in the widespread deterioration of the ecosystems that support all life. In fact, there is increasing evidence that growing numbers of people across the Earth experience “ecological grief” in response to climate change ([Cunsolo and Ellis, 2018](#)). When such grief is ignored, psychological symptoms such as depression and anxiety can emerge.

Depression and anxiety, which often are “comorbid,” or occur together, can be thought of as symptoms of our ongoing attempt to numb painful experiences. Perhaps one of the most painful and globally-widespread experiences today is the realization that climate change is real, that humans have largely contributed to it, and that many experts say that we have less than a few decades to reverse our behavior before even more dire consequences result. When people believe that they are powerless to do anything about this situation, as many do, the numbing can become even more profound. Not all depression and anxiety of course is related to A&B. However, symptoms of depression and anxiety that are related to climate change or other GSTs can be thought of as warning signals from our own human body-mind-spirit, that there is something we need to address, both within ourselves and in the world we live in.

Although the psychological is especially thought of today as having to do with mental activity, humans of course are also emotional beings. Emotions are sometimes understood to be reactions to what the mind thinks, and thus secondary to thought; another perspective is that emotions are primary movers and can drive thought. We do not have enough space in this chapter to further examine this debate, but we can point out that emotions are an important part of the EBPSS nature of a human being.

Healing the psychological dimension means in part that we individually and collectively recognize and address the symptoms that we suffer from as we watch the quality of our living environments steadily decline.

The Sociological Dimension

Most of us are aware of inequities of distribution of wealth and power in our world. Fewer are aware of how different human populations are involved in and affected by destruction of our A&B.

There are in fact significant social justice issues. For example, about 102,000 people currently die annually from human caused fine particulate matter, and People of Color are disproportionately exposed to such pollution and become sick and die more often because of it (Thompson, 2019). In the short term, the physical and emotional costs of GSTs are felt most by the poor and disempowered, who are often most-exposed to changing conditions; in the long term, these costs will be increasing paid by all of our descendants (Shiva, 2015). There will be an estimated 200 million climate refugees by 2050 and the poorest countries, with the exception of Australia, will warm the most (Wallace-Wells, 2019). Costs to more developed nations are not negligible either however; for example extreme weather events cost the United States about 400 billion\$ from 2015 to 2018 (U.S. Global Change Research Program, 2018).

Paralleling our concerns about human diversity is the severe loss of biodiversity in other life forms. About 600 species have gone extinct over the past 250 years because of human activity. Although other life forms are being impacted the most at this point in history, the well-being and existence of human life will be increasingly threatened (Vaughan, 2019).

Sustainability can thus be framed as a social justice issue. The practice of supporting the wellbeing of A&B can be framed as an expression of an "Earth democracy" that includes for example, food democracy (questioning chemicals and genetic engineering) and water democracy (looking at who owns the water) (Shiva, 2015).

Healing of the social dimension begins when we become aware of who is most responsible for destruction of our A&B, and of who (including human populations and other life forms) are most vulnerable to the impact of this destruction.

The Spiritual Dimension

There is arguably a similarity between the way I treat myself, the way I treat other people and the way I treat the A&B in my life. This concept has been recognized by teachers in most of the world's wisdom traditions (Krishnamurti, 2019). For example, from the point of view of a number of religions, consumerism reinforces waste and a false identity based on possessions, promotes harm to A&B, and encourages attachment to materialism (Kaza, 2019).

The dimension of spirituality is not the same as religiosity. Whereas religiosity can be understood as a *social* dimension of human life involving shared rituals, beliefs, and doctrines; spirituality is usually defined as an *individual* dimension of human life involving the person's own search for meaning, purpose, and connectedness. An individual can see themselves as both spiritual and religious, as neither, or as one without the other. Spirituality has become increasingly important in the United States as a 75% majority now see themselves as spiritual, and as a rising number also see themselves as spiritual but not religious (Lipka and Gecewicz, 2017).

Not only do most of us live in our heads, as discussed above, we also typically identify with our thoughts. What does that mean? When I identify with my thoughts, I believe that I am my thoughts and my thoughts are me.

Such identification can be thought of as a function of the ego. The ego is the unexamined (usually unconscious) human mind that identifies with any form, especially mental forms, or beliefs. From a spiritual perspective, ego-identification is a primary cause of disconnection from myself, from other people, and from A&B. This is largely because the ego tends to see itself as special and separate, from other people, other life forms, and from the Universe that is our home (e.g., Tolle, 2005). The healing of ego requires consciousness; consciousness of ego is reverent (friendly) awareness of the power of ego in the present moment.

From a spiritual perspective, when we identify with our own species, we also hold conscious or unconscious negative biases towards other life forms. In a similar way, when human beings identify with nationality, religiosity, or other groupings; such identifications are often exclusive, in that people who are not members are viewed negatively. When people become conscious of their identifications, the power of the identifications tend to decrease. It may be quite possible, for example, to be a patriot and not hate people who live in other countries. Similarly, it might be possible to love humanity, without identifying so much with our species that we view all other life forms as inferior and expendable.

Thus, healing in the spiritual dimension involves consciousness of the ego's identification process, especially identification with beliefs.

Assessing Individuals and Communities with the Ecobiopsychosocialspiritual Approach

The ecology theorist and the mental health practitioner can use the EBPSS approach to understand and assess human behavior towards A&B, and to also assess the impact of those ecosystems on the well-being of individuals and human populations.

Fig. 3 Interconnected well-being.

From the EBPSS perspective, the well-being of humans is interconnected with the well-being of the A&B we live with. This idea is illustrated in **Fig. 3**. Individual and collective human well-being includes healthy development in all the EBPSS dimensions. Well-being of local anthromes and global biomes is also complex and includes the health of all the living things and of the ecosystems that support all life.

The basic assessment method is to examine each of the five dimensions of EBPSS in the individual and the community we are working with, and look for evidence of biophilia. Biophilia is a term created by [Wilson \(1986\)](#) to describe his theory that humans have a natural affiliation, or connection, with all life, similar to ideas advanced by [Tolle \(2005\)](#) and many other authors writing about the world's great wisdom traditions. The concept of biophilia can be expanded to include all the EBPSS dimensions; in other words, there is ecological, biological, psychological, social, and spiritual biophilia.

Biophilia can be assessed at all dimensions of human development. Biophilia is expressed on the ecological level, for example, when people in a community recognize and advocate for the well-being of the eco-systems they live in or near. One way biological biophilia can be recognized is by examining the awareness people have about how their physical health is connected with the quality of the air they breathe and the water they drink. On the psychological level of biophilia, awareness is directed towards the emotional and cognitive symptoms that are associated with ecological conditions and with the level of commitment to stewardship of A&B. Social justice is an indicator of sociological biophilia; and communities are assessed by the extent to which minoritized populations have access to healthy environmental conditions and resources. Finally, an example of spiritual biophilia is the extent to which our connection with nature is recognized and expressed in local faith communities and other spiritual groups.

When assessing the well-being of an individual; a healthy, whole person is understood to be aware of each of her five dimensions and can express those dimensions effectively and nonviolently. We can define empowerment as this ability to both be aware of and express ourselves in all our dimensions. Healthier people tend to recognize their connection with A&B; more empowered people tend to act to protect and enhance the well-being of A&B.

Case Study A: Assessment

For example, in case study "A" we select a 30 year old woman living in a city in the Midwest, USA. She reports to the social worker that she has been moderately depressed and anxious, with no suicidal ideation, for as long as she can remember. She reports that she lives alone, works full time for a dentist's office, and feels little connection with other people or the anthromes she interacts with. When she was a child she lived in the suburbs with her mother, and they seldom went outdoors. She is unhappy with the way her body looks, and frequently goes on diets that all ultimately fail to help her lose weight.

On the collective (macro) level, the Ecological theorist may want to understand why people in this city continue to vote down proposals to build more sustainable power sources, expand alternative low-energy transportation networks, purchase more urban green spaces, establish tighter emission controls, and regulate pollution into local streams and lakes. The community mental health practitioner may also want to understand how much of the depression and anxiety seen in people living in this urban anthrome is connected with the well-being (e.g., air quality, extent of green space, commuting times, population density, etc.) of the anthrome. Both quantitative and qualitative surveys may provide useful data that helps answer these kinds of questions.

On an individual (micro-mezzo) level, the mental health practitioner may want to assess how much of this young woman's depression and anxiety is related to the deteriorating conditions of her local urban anthrome and global biomes. Such an assessment may have to be largely based upon self-report by the woman during a clinical interview.

Several other ways to assess the possible correlations between anthrome and biome well-being and human well-being include (1) observing what happens when people empower themselves to try to improve their own well-being and the well-being of their

local anthromes and regional biomes, rather than feeling numb and helpless and (2) exposing people to healthier environments and measure any changes in their well-being. The social worker could use both of these strategies in her ongoing assessment of this woman.

Intervening with Individuals and Communities with the Ecobiopsychosocialspiritual Approach

Is it possible to help people empower themselves to transform their relationships with their local anthromes and global biomes? Since current attitudes and behaviors regarding other life and ecosystems appear to be largely learned over the millennia of human civilization, it seems reasonable to assume that these dysfunctional learnings can also be unlearned, and replaced with healthier attitudes and beliefs. Because of the rapid intensification of Global Survival Threats (GSTs) today, such as climate change and preparations for war, such relearning may need to take place relatively quickly, over decades rather than over millennia, and thus effective individual and collective interventions are required.

Multi-dimensional interventions are available on both the micro/mezzo (individual, family, small group) and mezzo (local and global community) levels. Some of these are summarized in Fig. 4. This table organizes interventions along three levels of analysis; (1) micro, mezzo, and macro; (2) indoor and outdoor activities; and (3) EBPSS dimensions. The most effective intervention strategy is viewed as inclusive; in as much as it includes interventions drawn from all of these three levels of analysis. Ecologists and mental health practitioners can partner in developing and utilizing a broad array of interventions that address not only all of the EBPSS dimensions, but also the micro, mezzo, and macro levels of humanity. Brief descriptions of the interventions in Fig. 4 are offered below. The EBPSS approach is not designed to replace more conventional and currently popular approaches to psychotherapy, but is rather designed to be added to such approaches.

Indoor Micro and Mezzo Interventions

Animal assisted therapy helps connect people with their own bodies and with nature, often through interactions with such often human-friendly animals as dogs, cats, and horses. Cognitive-Behavioral work can help people change their beliefs systems about and behaviors towards A&B. Social workers can also use guided visualizations and artistic expressions (such as drawing, music, and dance) to help people examine and express their feelings about life and the ecosystems that support life.

Environmental dialogues are structured conversations on ecological topics. Guidelines for dialogue are utilized in these conversations, and topics might include such controversial issues as urban air pollution regulations, creation of new national monuments, and decisions about energy extraction on public lands. Consumer strategies give people an opportunity to empower themselves to become agents for change by using their purchasing power to, for example, reduce plastic pollution and encourage alternative energy and farming approaches. Finally Transpersonal therapy can help people explore the relationship between their spirituality and the well-being of A&B, and ego-identification work can help us become conscious of our biases about other living things and the ecosystems that support all life.

Outdoor Micro and Mezzo Interventions

Outdoor retreats can be shared experiences for community members who want, for example, to change local attitudes and public policies towards their local anthromes, and such events can target different neighborhoods, age groups, or other populations.

Location	Micro-mezzo levels	Macro level
Indoors	Animal assisted therapy (Bio) Cognitive-Behavioral work (Psych) Guided visualizations (Psych) Artistic expressions (Psych) Environmental dialogue (Soc) Consumer strategies (Soc) Transpersonal therapy (Spir) Ego-identification work (Spir)	Education for children, youth, adults (Eco) Indoor Environmental Quality (Eco) Advocacy for clean air and water (Eco) Population control initiatives (Eco) Voter organization (Soc) Lobbying (Soc) Community dialogues (Soc) Environmental justice work (Soc)
Outdoors	Outdoor retreat (Eco) Identifying sacred landscapes (Eco) Nature walk (Eco) Equine therapy (Bio) Home gardening (Bio) Vision quest (Spir)	Urban planning and architecture (Eco) Community environment projects (Eco) Re-wilding projects (Eco) Outdoor service-learning sites (Eco) Holistic/organic agriculture (Bio) Community gardening (Bio)

Fig. 4 Examples of ecobiopsychosocial approaches in social work practice. Adopted from Derezotes, D. S. (2016). *Ecopsychology: Adding “eco” to the biopsychosocialspiritual perspective*. In Turner, F.J. (Ed.) *Social work treatment: Interlocking theoretical approaches*, 6th edn. Oxford: Oxford University Press.

Individuals can also reconnect with nature by identifying the landscapes that are sacred to them, such as a particular mountain location, river valley, or forest grove and then by visiting these locations. Nature is often a wonderful healing force for people, and nature walks and equine therapy (which could involve simply riding a horse on a trail) are two examples of ways to involve people in natural settings. Interactions with plants can also be healing, and people can become involved in raising their own vegetables and fruits, even in intense urban environments. Finally, a vision quest is usually a solo time spent camping outdoors, during which the individual practices rituals that are spiritually meaningful to her.

Indoor Macro Level Interventions

Ecology and mental health curricula for children, youth, and adults can become required content in public and private school settings. Such content can be both informational (e.g., include climate change data) and self-reflectional (e.g., include exercises designed to encourage self-awareness of connection with nature). Both students and employees can be given opportunities to participate in evaluating and modifying Indoor Environmental Quality as well as to advocate for local clean air and water. Dialogues on, for example, population control initiatives can also be held for community members, during which participants listen to the ideas and concerns of others.

Both students and other community members can be given opportunities to participate in voter organization efforts, during which “Green” (see Wall, 2010) issues are discussed and voted upon. Later, participants can help with lobbying efforts in local, state, and federal settings, in favor of agreed upon issues. Additional community dialogues can be held on a number of Green issues, where people of different political persuasions agree to meet, speak respectfully, and listen for understanding. Finally, community efforts can include environmental justice work, in which people focus upon understanding and changing environmental injustices, such as for example, the plight of local children of poor families who are especially exposed to noisy polluted streets.

Outdoor Macro Level Interventions

Institutions and communities can support Green urban planning and architecture, by implementing new policies, guidelines, and funding opportunities. For example, clean alternative energy projects can be supported financially, rather than penalized, and non-polluting transportation options such as bicycle commuting can be supported through construction of safe community bike lanes and tax incentives.

Communities can also participate in re-wilding projects, in which people help re-create land and water areas where natural living systems can restore themselves. Outdoor service-learning sites can be established in various more-natural areas, where students and others can visit and learn more about the local A&B.

Finally, holistic/organic/regenerative agriculture projects can be developed where local people can volunteer or work to support the production of local healthy food. Within urban areas, community gardening projects give people an opportunity to not only grow their own healthy food, but also to meet other people with similar interests.

Case Study A: Intervention

In follow-up to these brief introductions to these interventions above, we can continue looking at our case study “A” that we began to look at earlier in this chapter. We can now address EBPSS interventions that might be used with the depressed young woman and her community in a city in the Midwest, USA.

The mental health social work practitioner might assess that the young woman has little connection with A&B on any of the EBPSS levels, and that this disconnection is probably a factor related to her depression and anxiety, along with such other factors as her past trauma, relationships, vocational issues, etc. The client’s strongest connection is in the cognitive (psychological) level, because she has above average intellectual intelligence, and understands intellectually, if not emotionally yet, that she is disconnected from her world. The social worker plans to first build on the client’s intellectual strength as she strives to help the client reconnect with her own body, with other people, and with the environment she lives in.

The social worker, or other professional helper, begins by engaging with the woman and forming a helping relationship. She might intervene first by helping the client understand intellectually, and perhaps later also feel, how disconnected she is with her own body, with other people, and with the environments she lives in. She might ask the client if she would like to experience a reconnection with her own body, with other living things, and with the ecosystems that support all life.

The social worker tries to find interventions that fit with the client’s strengths, interests, and cultural context. Since this client is creative and artistic, they agree that she will keep a journal in which she will do some writing and drawings of her experiences. Since the client is especially interested in going outside on a solo experience and has expressed interest in spirituality, they also agree that she will go a vision quest for a night by herself in the closest and safest biome area that is available to her, and do a journal of her experience.

The social worker realizes that the client’s depression and anxiety is not only related to climate change and disconnection with her own body-mind-spirit. She thus also conducts more traditional interventions that help the client address past trauma, current relationships, and work satisfaction, for example.

The social worker, in addition to doing psychotherapy, is also a community organizer and activist. She belongs to a group of local activists that includes ecologists who teach at the local university, students, and other community members. They call

themselves the “Green Giants” and they meet regularly to support each other, identify local and regional issues, and plan responses. Since they realize that a small group of activists cannot take on every issue, they decide to focus this year on the deterioration of the local water and air quality. They start out by hosting a water and air dialogue in a small town 50 miles from the city center, and they invite local farmers and ranchers, city dwellers, and students. They begin the dialogue by setting out guidelines for conversation, especially emphasizing the importance of listening for understanding and speaking respectfully. The conversation is well-attended, and although there is not an agreement on all topics, new relationships are initiated which can lead to further local cooperation around issues that matter to everyone.

Conclusion

In conclusion, the largely human-caused conditions that now threaten the well-being of our A&B also threaten the well-being of all humans on the planet. As these conditions become increasingly serious, we are now seeing a growing recognition that this threat is real, by increasing majorities of people, across cultures, nationalities, and religiosities. This global crisis is thus also becoming an opportunity for global transformation.

In this chapter we looked at how human beings have lost connection with our own bodies, our fellow human beings, other living things, and the ecosystems that support all lives. We examined how this disconnection is related to physical, psychological, and spiritual symptoms that also call to us for recognition and action.

We looked at ways that ecologists and mental health practitioners can work together with multidisciplinary teams to understand and address the root causes of human contributions to the global survival threat of increasing deterioration of our local and global anthromes and biomes.

We offered what we are calling an ecobiopsychosocialspiritual approach to addressing this threat, that starts with the recognition of our own human multidimensionality, of body, mind, and spirit, and that expands upon the idea of biophilia to include the five interrelated EBPSS dimensions. We created a beginning practice model for assessment and intervention across the micro, mezzo, and macro levels of change. We suggest that practitioners and policy makers utilize interventions from all the levels and dimensions, in our efforts to help people transform how we think about and behave towards our A&B.

Much more research can be done to better understand the interconnections between anthrome, biome, and human well-being, and to test the efficacy of the interventions we have looked at, but we already know enough to begin to do more today, to educate, intervene, and transform ourselves and our communities. The well-being of life on our planet is at stake.

Abstract

Promoting voluntary behavior change is a central research topic in environmental psychology. Thus one would expect to find a huge body of research analyzing the dynamic nature of voluntary behavior change processes as well as their psycho-social drivers. However, reading the existing literature with this expectation is quite disappointing: It is still dominated by cross-sectional studies using psycho-social constructs derived from a limited number of theoretical frameworks to predict behavioral intentions. Thus the central assumption underlying our article is that environmental psychology urgently needs two things: (1) More research analyzing the actual course of behavioral change processes, and (2) newer and more diverse theoretical perspectives for explaining the different stages of behavioral change processes. For this purpose the article systematically adopts in a first step results of health psychology: Here a similar discussion resulted in the identification of five overarching themes representing theoretical explanations for different stages of behavioral change processes: motives, self-regulation, resources, habits, and environmental/social influences. In a second step we present the stage model of self-regulated behavior change (SSBC) as an example for a theoretical framework which integrates different theoretical themes into one testable model. In a third step we summarize the already existing research testing hypotheses derived from the SSBC.

Introduction

Most environmental psychologists view understanding the psychological processes of voluntary behavioral change as a central task of their subdiscipline. Thus one would expect to find a lot of theoretical and empirical work on the phenomenon of how people actually change their behavior. For example, the process displayed by Fig. 1 suggests how the change of a specific behavior might proceed.

The graph describes a fictive person's behavioral change process from the habit to use the car for commuting by bike over a time period of 20 weeks. The grey line indicates the intensity of car use for commuting, the black line the intensity of bike use for commuting. Whereas from week 1–5 the person shows a stable preference for using the car, in week 6 one can observe the initiation of a sudden and drastic behavioral change: Within a few days the previously high car use decreases drastically, whereas the previously low cycling frequency increases drastically. This observable behavioral change is probably the consequence of a longer preceding mental process leading to a fundamental re-evaluation of the two behavioral alternatives 'commuting by car' vs. 'commuting by bike.' For this reason, understanding the mental process which leads to the re-evaluation of competing behavior alternatives is the first central research interest of environmental psychology.

After the initiation in week 7–10 commuting by bike becomes the dominant behavior (area A in Fig. 1). But in week 11 obviously something happens (e.g., longer period of bad weather, illness, work overload, stress within the family) which causes car use to become the person's dominant behavior (area B in Fig. 1) again. Such lapses are typical for behavioral change processes. However, in the present case the person can activate factors and processes which help him or her to overcome this 'crisis' and to install cycling again as dominant behavior for commuting. For this reason, understanding which factors cause these 'crises' and which factors and processes help to reestablish the new behavior after a relapse is a second central research interest of environmental psychology.

Fig. 1 Dynamic and stages of voluntary a behavior change process. From Kwasnicka, D., Dombrowski, S.U., White, M., and Sniehotta, F. (2016). Theoretical explanations for maintenance of behaviour change: A systematic review of behaviour theories. *Health Psychology Review*, **10**(3), 277–296.

From week 16–20 the person shows a stable preference for cycling which indicates that cycling is likely to be maintained as the dominant behavioral response over a longer time period. For this reason, analyzing the psycho-social factors and processes which influence the long-term maintenance of behavioral change is a central third research interest of environmental psychology. In summary, researching the psycho-social factors and processes underlying behavioral change with the psychological re-evaluation and the successful initiation of behavior, successfully overcoming relapse and maintenance of new behavior are central research interests of environmental psychology.

Aim of the Present Article

The aim of the present article is to review and summarize theoretical approaches and empirical results to answer the three fundamental questions from the previous section. This means investigating the nature of voluntary behavioral change processes in all facets from initiation over successfully overcoming relapses to long-term maintenance. The idea is that empirically supported answers to these questions can provide a good starting point to develop effective interventions which support behavioral change.

A Disappointment

However, approaching the literature with the expectation to find a huge body of research papers discussing and explaining behavioral change processes is disappointing. The field is still dominated by cross-sectional papers applying static predictor models to explain self-reported behavioral change intentions. There are some important papers providing meta-analytical summaries of the effectiveness of behavioral change techniques (e.g., Abrahamse et al., 2005; Osbaldeston and Schott, 2012; Lokhorst et al., 2013; Abrahamse and Steg, 2013). But still, these papers only analyze the (mostly short-time) behavioral effects of intervention techniques without referencing theoretical models of the underlying behavioral change process. We found only one study (Klößner, 2014) which uses a model of behavioral change and analyses the temporal dynamic of the decision-making process to purchase an e-car across 90 days.

Behavioral Change Research Within Health Psychology

Because ending our article here would be a frustrating and less constructive contribution, we looked into the literature of another psychological subdiscipline—health psychology—to find more systematic research on behavioral change processes. Indeed, in the last decades health psychology has invested considerable effort to systematically investigate how to design effective, theory-based behavioral change interventions. For the purpose of our article a systematic literature review conducted by Kwasnicka et al. (2016) provides a good overview which theoretical perspectives may be stimulating for further environmental psychological research. With a systematic data-base search Kwasnicka et al. (2016) identified 100 theories which include factors or processes helpful for describing and understanding the dynamic processes underlying different stages of behavior change. The authors used an elaborated synthesis approach and clustered the 100 theories into five overarching, interconnected themes: Motives, self-regulation, habits,

resources and contextual factors. We are convinced that systematically reviewing these theoretical themes may be stimulating to further develop the behavioral change research within environmental psychology. For this reason the next five sections provide a brief summary of the five theoretically influential themes identified by Kwasnicka et al. (2016).

Theme 1: Motives for Initiating and Maintaining Behavioral Change

Motives are central drivers of the initiation as well as maintenance of voluntary behavioral change: They help establishing priorities and allocating material and psychological resources. Whereas behavior change is often initiated to avoid negative long-term consequences (e.g., stopping ongoing climate change, norm activation model—Schwartz, 1977), the motives to maintain the new pro-environmental behavior are often different from these initiating ones. Motives are particularly facilitating for maintenance if they enable regular gratification from enacting the new behavior: This includes enjoying to do the behavior as such, or enjoying the immediate outcomes of the behavior (theory of planned behavior—Ajzen, 1991). Furthermore, whereas the initiation of behavioral change is often extrinsically motivated, for the maintenance of new behavior intrinsic motivation has to replace extrinsic motivation (i.e., the individual wants to maintain the new behavior itself, self-determination theory—Deci and Ryan, 2000). Especially intrinsically motivating is the perception that the new behavior is in line with central beliefs a person has about him- or herself (self-identity; self-schema theory—Markus, 1977; Van der Werff et al., 2013). Of course self-identity and nested beliefs and values can change as a result of engaging with a new behavior. Such changes in identity positively enhance behavior change maintenance. For instance, a person who cycles to work regularly can develop the self-representation of being an environmentally responsible person. Having a new self-representation of being environmentally responsible, makes it more likely to cycle to work in the future too.

Theme 2. Self-Regulation

Self-regulation includes the processes of self-monitoring, self-evaluation and self-reinforcement as well as dealing with temptations, and hedonistic and impulsive influences that are in conflict with the goals behind behavioral change (Baumeister et al., 1994). Individuals differ in their skill to deal with these situations. In other words, they have a different 'self-regulatory capacity' (temporal self-regulation theory—Hall and Fong, 2007). These differences in self-regulatory capacity are hypothesized to reflect executive control functions (e.g., planning skill, inhibition control, task switching) and they explain the ability to override automated behavioral responses (Nederkooym et al., 2010).

Analyzing the behavior change process with the perspective of active self-regulation it becomes apparent that self-regulation decreases over time: Individuals initiate behavior change when the moment is right, e.g., at times when opportunity costs and goal conflicts are low and motivation and capacity high. However, after initiating behavioral change they are confronted with context-specific cues, changes in options and opportunity costs or varying levels of motivation. These factors may increase the risk of behavioral relapses. In response to situations with a high risk of relapse, individuals may apply effective coping responses. As a result of their self-efficacy they expect more positive outcomes and the probability of future relapse decreases (relapse prevention theory—Marlatt and George, 1984). Nevertheless, individuals may fail to apply effective coping responses in high risk situations. As a result their self-efficacy and positive outcome expectancies decrease. As a consequence individuals often return to their prior behavior and their probability of future relapses increases (Marlatt and George, 1984).

Theme 3. Habits

Dual process models of behavior assume that behavior is governed by the interplay of two regulatory systems: a reflective system, which is based on conscious deliberation, controlled but effortful, and a quicker automatic system that controls habits and impulses (dual-system models—Strack and Deutsch, 2004). To maintain new behavior individuals can do so through ongoing self-regulation via the reflective system. However, self-regulation draws on finite cognitive resources which can be depleted. When cognitive resources are low the 'costly' self-regulation is likely to fail. Thus, the most promising mechanism to maintain a newly adopted behavior is to perform it in a habitual way.

Habits are behavior that has become automated and is triggered by situational cues (Lally et al., 2010; Verplanken and Wood, 2006). They develop over time with repetition and are theorized to be performed outside of conscious awareness (Hofmann et al., 2008; Verplanken and Aarts, 1999). With that said, when trying to create new habits one should not forget the power of 'old' habits. The stronger prior habits are, the more likely an individual is to relapse to the prior behavior. Removing situational cues that may trigger previous behavior therefore can support the maintenance of behavior change with the help of stimulus control (transtheoretical model of change—Prochaska and DiClemente, 1983). In brief, the processes of breaking old habits and developing new ones are likely to act in conjunction for behavior change maintenance.

Theme 4. Resources

Resources are understood as psychological and physical assets that can support the process of behavioral regulation. As maintaining a new behavior is often difficult and requires sustained efforts, resources, which an individual can use in the process, are hypothesized to play an important role. For example, when cognitive resources are limited or depleted due to stress, tiredness, exhaustion and intoxication, an individual's self-regulatory capacity is minimal. Individuals are more likely to initiate behavior change at times when their psychological and physical resources are plentiful and when opportunity costs (effort needed to enact behavior) are low (i.e., resources are not immediately needed for competing demands). Lapse and relapse are thus, associated with low levels of resources.

The dual process models offer an explanation how resources impact behavior change processes. It is hypothesized that resources act as moderators (boundary conditions) on which system generates a behavioral response: Are there enough resources for the resource intensive reflective system or only enough for the resource sparing impulsive system (impulsive versus reflective framework—Hofmann et al., 2008; dual-system models—Strack and Deutsch, 2004)? In short, when cognitive resources are limited effective maintenance of behavior occurs mainly when the behavior is habitually instigated.

Theme 5. Environment and Social Influences

The final theme includes features of the social and environmental context of action. This theme includes aspects of the choice architecture that alter the opportunity costs and accessibility of behavioral options (Thaler and Sunstein, 2009). Many theories emphasize the role of a supportive external environment on behavior change processes. For example, habit theories (Hofmann et al., 2008; Verplanken and Aarts, 1999), hypothesize that environmental cues related to prior and newly adopted behaviors explain whether or not a newly adopted behavior is maintained. A supportive environment facilitates behavior change as it lowers the opportunity costs of the new behavior (with e.g. providing available options, setting incentives and disincentives and influencing opportunity costs and cues). Environmental factors determine the amount of active self-regulation and resource required by the individual. Thus, behavior change is less likely to be maintained in environments which are not conducive of the newly adopted behavior (Mackenbach et al., 2014).

Like environmental factors, social influence affects the choice architecture too. This means that the opportunity costs and incentive structure for behavioral options in a given context is influenced by social interactions too. For example, knowledge and skills can be acquired through social modeling (social cognitive theory—Bandura, 1986). Individuals may follow the guidance of people they trust and they feel connected to (Bandura, 1986). In short, the social influence of peers also impacts one's own maintenance of behavior change. Table 1 again summarizes the five theoretical themes and why they are important for understanding voluntary behavior change.

Table 1 Theoretical themes relevant for the behavioral change process.

Themes	Brief theoretical explanation	Theories included (examples)
(1) Motives	The motive to avoid negative long-term consequences is important for initiating behavioral change. People tend to maintain their new behavior if they have at least one sustained maintenance motive, i.e., they are satisfied with behavioral outcomes, they enjoy engaging in the behavior; if behavior is congruent with their identity, beliefs and values	Norm activation theory (Schwartz, 1977) Theory of planned behavior (Ajzen, 1991) Self-determination theory (Deci and Ryan, 2000) Ecological self-identity (Van der Werff et al., 2013)
(2) Self-regulation	People tend to maintain behavior if they successfully monitor and regulate the newly adopted behavior and have effective strategies to overcome barriers to the performance of the new behavior	Self-regulation theory (Baumeister et al., 1994) Relapse prevention theory (Marlatt and George, 1984) Dual process model of self-control (Hofmann et al., 2008)
(3) Resources	People are successful in initiating and maintaining behavioral change if their psychological and physical resources are plentiful	Reflective and impulsive model (Strack and Deutsch, 2004) Self-control theory (Baumeister, 2002)
(4) Habit	Strong old habits are a central barrier for initiating behavioral change, creating new habit facilitates the maintenance of the new behavior	Habit theory (Verplanken and Aarts, 1999; Verplanken et al., 2008)
(5) Environmental and social influences	A supportive environment and social support are important for initiating and maintaining behavioral change	Social cognitive/learning theory (Bandura, 1986)

Adapted from Kwasnicka, D., Dombrowski, S.U., White, M., and Snihotta, F. (2016). Theoretical explanations for maintenance of behaviour change: A systematic review of behaviour theories. *Health Psychology Review*, 10(3), 277–296.

Stage Models of Behavioral Change as Integrative Conceptual Frameworks

The presented theory themes identified by Kwasnicka et al. (2016) provide a multitude of factors and processes which are potentially relevant to understand behavioral change processes. However, systematic empirical research on behavioral change processes needs an integrative conceptual framework to provide a general understanding of the dynamic and structure of the behavioral change process. Such a conceptual framework is also necessary to systematically derive and empirically test research hypotheses about the behavioral change processes. So-called stage models of behavioral change are becoming increasingly popular as integrative conceptual frameworks of behavioral change processes. Stage models of behavioral change were introduced by Lewin (1952) who stressed the temporal dimension of behavioral change and considered it a process rather than an event. More precisely, he describes behavioral change as a transition through three stages, which he called unfreezing, moving, and refreezing. The transtheoretical model (TTM; Prochaska and DiClemente, 1983) presents an updated version of this idea. The TTM also characterizes behavioral change as a transition through qualitatively distinct stages and additionally formulates that people face stage-specific hindrances. To overcome these, people need stage-specific skills and strategies. The TTM describes the following five stages of change: precontemplation; contemplation; preparation, action, and maintenance. Further the TTM assumes that in most cases behavioral change is not a linear but a cyclical process. Barriers and resistances can keep people fixated at an early stage of change for a long period of time. Frequently, they relapse back to the beginning of the process.

In the literature the TTM has been criticized as a descriptive model that does not provide a convincing theoretical rationale for the postulated five stages as well as the processes triggering stage transition (e.g. West, 2005). The stage model of self-regulated behavioral change (SSBC) developed by Bamberg (2013a,b, see also Klöckner, 2015) provides such a theoretical rationale. For this purpose, the SSBC combines assumptions from the TTM, the model of action phases (Gollwitzer, 1990), the theory of planned behavior (Ajzen, 1991), and the norm activation theory (Schwartz, 1977). The main assumption of the SSBC is that people can change even strongly habitualized behavior, if they are motivated to do so. The SSBC describes this process from abstract motivation to concrete behavior as a series of four stages: (a) predecision stage, (b) preaction stage, (c) action stage, and (d) postaction stage (see Fig. 2).

According to the SSBC, successful behavioral change follows these four stages but setbacks and repetitions may occur between stages. Each stage has its specific challenge, and transitioning from one stage to the next means to cross a threshold of setting a specific intention. First, in the predecision stage, the individual addresses the question why behavioral change is necessary. Drawing upon the example of voluntarily reducing car use, the question in this stage is: "Why is it important to reduce my car use?" The individual has to form a general goal-intention to take action: "In the next few weeks, I intend to reduce my car use". The SSBC predicts, that this intention is influenced by an activated personal norm to reduce car use. This personal norm is defined as a feeling of moral obligation to act. It is triggered by becoming aware of negative consequences of one's behavior (e.g. negative consequences of my car use for the environment and quality of urban life), ascribing responsibility for these consequences to oneself, and the presence of social norms that one is socially expected to reduce car use (e.g. social pressure or support to reduce my car use). The variables and mechanisms determining the goal-intention are derived from the norm activation theory (Schwartz, 1977).

Once the general goal-intention of reducing car use has been set, the individual proceeds to the preaction stage. Before the background of the now existing general car use reduction goal intention, in this second stage of the behavioral change process the relevant question is: "Which action should I take to reduce my car use?" For this purpose the person evaluates his or her attitude towards different alternatives such as walking, using public transportation, cycling, and how easy he or she perceives the implementation of these alternatives (perceived behavioral control, PBC). Attitude and PBC are two constructs taken from the theory of planned behavior (Ajzen, 1991) and they pave the way to the next threshold: developing a behavioral intention.

Fig. 2 The stage model of self-regulated behavioral change (SSBC, Bamberg, 2013a).

Here, the person picks a behavior with the best attitude-difficulty-balance for him or herself. Forming this behavioral intention (e.g., “In the next few weeks, I intend on using my bicycle instead of my car to commute to work”) marks the transition from the preaction to the action stage. In this third stage of the behavioral change process the implementation of the chosen behavior needs to be planned. The obstacle to address is: “How do I implement my intended behavioral change?” The ability to plan and remove barriers is the main driving force during this stage. The transition to the last stage is indicated by forming an implementation intention, e.g.: “Tomorrow morning at 7 a.m., I intend to use the Victoria Road for cycling to my company’s building”. In this fourth postaction stage behavioral changes need to be stabilized, and relapses to old behavior have to be dealt with. The ability to recover from a relapse is the main predictor to stabilize a new behavior and to make it a new habit.

Altogether, the model assumes that the transition through the four stages is marked by three critical transition points. Each reflects the successful solution of stage-specific tasks: to form a goal intention, a behavioral intention, and an implementation intention. The greatest strength of the SSBC lies in its detailed description of the task a person has to solve in each of the four stages as well as the specific cognitive ‘mindset’ people need to adopt for solving them.

Implications for Interventions

The ultimate goal of the SSBC is to provide a conceptual framework to systematically develop interventions which support voluntary behavioral change. One practical implication of considering behavioral change as a transition process through different stages is that instead of thinking of one single intervention for all, specific intervention packages have to be developed for meeting the needs and barriers of a specific stage. For instance, interventions targeting people at the predecision stage are more likely to be successful if they concentrate on providing information that can increase both problem awareness and perceived personal responsibility. Also, interventions which activate social and personal norms are likely to be important in this stage. Second, individuals who have set a goal-intention need information concerning the availability and the pros and cons of different behavioral alternatives. Third, individuals who intend on switching to an alternative behavior probably benefit most from interventions supporting the implementation and initiation of this intention, e.g. detailed behavioral planning. Fourth, individuals who already implemented a new behavior profit from intentions which decrease the temptation to relapse. Table 2 presents an overview of stage specific intervention strategies.

Results of Empirical Test of Hypotheses Derived From the SSBC

Valid and reliable measurement instruments are a prerequisite for empirically testing hypotheses derived from the SSBC. In the meantime for all SSBC constructs such measures have been developed and tested in different behavioral contexts (e.g., Bamberg, 2013a,b; Klöckner, 2014). As an example Table 3 presents a short instrument for assessing a person’s current stage of change.

Bamberg (2013a) provides first correlational evidence for the SSBC’s assumptions with regard to the relationships between the various constructs integrated in the model. Klöckner (2014) examined central SSBC premises by studying the decision-making process when purchasing e-cars. For this purpose, 90 participants completed measures of the SSBC constructs 30 times over a period of 60 days. This design allowed for directly testing the chronological dynamics of behavior change processes. Klöckner’s results supported the following SSBC assumptions: (1) In 85% of all transitions observed, participants moved a single stage forward or backward. Only a small number of participants skipped stages when transitioning. (2) Transitions from one stage to the next were preceded by changes in the respective type of intention. The intentions postulated by the model were meaningful predictors for subsequent behavioral changes, lending strong support to their assumed causal relationship. (3) Prior changes in the stage-specific social-cognitive constructs predicted changes of intentions.

To test the effectiveness of SSBC as a guideline to design interventions, Bamberg (2013b) developed and evaluated a SSBC-based social marketing campaign aiming to reduce car use. Based on an initial diagnosis of their current stage membership, participants

Table 2 Stage specific intervention strategies.

<i>Stage of change</i>	<i>Intervention strategies</i>
Predecisional	Make social and personal norms salient (e.g. Goldstein et al., 2008) Enhance problem awareness and self-focus (e.g. Prochaska et al., 2002) Enhance goal setting and goal commitment (e.g. McCalley and Midden, 2002)
Preactional	Provide information about the pros and cons of behavioral alternatives and enhance perceived behavioral control (e.g. Fishbein and Ajzen, 2011)
Actional	Support behavioral planning (e.g. Gollwitzer, 1999)
Postactional	Provide behavioral feedback (e.g. McCalley and Midden, 2002) Prevent the temptation to relapse (e.g. Marlatt and George, 1984)
General strategies	Provide social support (e.g. Hogan et al., 2002) Changes objective context conditions

Table 3 A short instrument for assessing a person's current stage of change concerning car use.

<i>Question: Which of the following statements best describes how you feel about your current level of car use for daily trips (in city X/ to your workplace) and whether you have any plans to try to reduce some or all of these car trips?</i>		<i>Stage allocation</i>
Please choose which statement fits best to your current situation and tick only one box		
At the moment, I use the car for most of my trips. I am happy with my current level of car use and see no reason why I should reduce it	☐ 1	Predecisional
At the moment, I still use the car for most of my trips. I would like to reduce my current level of car use, but, at the moment, I feel it would be impossible for me to do so	☐ 2	
At the moment, I do use the car for most of my trips. I am currently thinking about changing some or all of these trips to noncar modes, but at the moment I am unsure how I can replace these car trips, or when I should do so	☐ 3	Preactional
At the moment, I use the car for most of my trips, but it is my aim to reduce my current level of car use. I already know which trips I will replace and which alternative transport mode I will use, but, as yet, I have not actually put this into practice	☐ 4	Actional
Because I am aware of the many problems associated with car use, I already try to use non car modes as much as possible. I will maintain or even reduce my already low level of car use in the next months	☐ 5	Maintenance
As I do not own/have access to a car, reducing my level of car use is not currently an issue for me	☐ 6	'Captives'

were assigned to the corresponding intervention. The stage-specific intervention elements consisted of personal phone calls and information leaflets, aiming at activating and changing the underlying social-cognitive constructs of the three different intention types. An RCT-design was used for evaluating the campaign's efficacy. The results indicated that participants in the intervention group used public transport significantly more often and used the car significantly less often than the control group. Exhibiting an effect size of $d = .56$, the impact of the SSBC-based intervention on the reduction of car use was about three times stronger than the effects of traditional social marketing campaigns. In addition, there is evidence how the SSBC can be used as a theoretical foundation to construct a behavior change support system, which is web-based, to promote pro-environmental behavior (Bamberg et al., 2015; Mack and Tampe-Mai, 2016; Sunio et al., 2018).

Finally, Keller et al. (2019) published a first systematic review on papers applying the SSBC. They reviewed 10 studies published between 2013 and 2018, six of them were cross-sectional, three were intervention studies and one a correlational longitudinal design (for an overview please see Keller et al., 2019). According to Keller et al. (2019) the cross-sectional and longitudinal studies generally support the SSBC model, although there are some irregularities that warrant further investigation. The intervention studies found stage-tailored information to be more effective in promoting stage progression and behavioral change than nonstage-tailored information. Furthermore, Keller et al. (2019) identified several challenges that researchers may face when applying the SSBC. These include whether and how to analyze multiple, alternative behaviors; how to address the challenge of measuring a comprehensive model while keeping questionnaire length manageable; selecting and defining the role of model constructs in a behavioral context while keeping results comparable; and establishing a validated and reliable tool to diagnose a person's stage of change. Based on these insights, Keller et al. (2019) develop recommendations for researchers to design SSBC studies, which support the advancement of the theory and will then serve both researchers and practitioners for promoting pro-environmental behavior.

Coping Planning and Behavior Change—Research Stimulated by the SSBC

The SSBC also provides a theoretical background for reviewing the existing research on behavioral change processes. This review would indicate that most of this research is currently focusing on the first two stages of behavioral change, namely the predecisional and preactional stages. Research analyzing the factors and processes contributing to the successful implementation as well as maintenance of behavior change (actional and postactional stages) are still rare within environmental research. A recent study by Hsieh et al. (2017, 2019) provides one example for research questions and results which focus on these later stage of behavioral change. More precisely Hsieh et al. (2017, 2019) analyze the role of another volitional construct: Coping planning (Schwarzer, 2008; see also Fig. 2). Coping planning comprises actually enacting and maintaining the intended behavioral change. They assume that both volitional constructs—implementation intention and coping planning—are important in situations with a high risk of relapse. Implementation intention translates a goal into action by a mental link between situational cues and goal-directed responses in the form of “if—then”. In contrast to implementation intention, coping planning involves both anticipation of potential barriers which emerge during performing the actions, and ideas of how to overcome these barriers. As a result, the two planning cognitions may function differently in behavior change: Implementation intention plays an important role in initiating action, whereas coping planning may be more influential in the maintenance of behavior (Sniehotta et al., 2006; Ziegelmann et al., 2006). Supporting this theoretical assumption Hsieh et al. (2017, 2019) found in a randomized experimental intervention study that implementation intention and coping planning independently mediated the effect of behavioral intention on car use reduction. Additionally, coping planning partially mediated the effect of implementation intention on car use reduction. Furthermore, the results also supported the effectiveness of the combined implementation-intention-plus-coping-planning intervention in reducing car use, but not of the implementation intention alone intervention.

Conclusion

If behavioral change constitutes indeed a central environmental psychology topic, environmental psychologists have to invest more effort in researching the dynamic as well as psycho-social drivers of voluntary behavior change processes. Correlational studies with a focus on single psycho-social constructs to statistically predict behavioral intentions are cross-sectional snapshots of a change process and therefore not very helpful. Instead, more experimental longitudinal field studies are urgently needed, to analyze behavioral change processes over a longer time period in a natural setting. Furthermore such studies should be guided by explicit theoretical models of behavior change processes. The presented SSBC provides one empirically supported conceptual framework. The above presented study by Klöckner (2014) provides a good example for this kind of studies. Using the SSBC as a theoretical reference also indicates that research focusing on the later stages of behavioral change—behavioral initiation and maintenance are urgently needed. The presented study by Hsieh et al. (2017, 2019) provides a good reference point for this kind of research. In summary, from our point of view the SSBC provides a starting point for more research on voluntary behavior change processes in environmental psychology. We are convinced that future research will result in more detailed and realistic theoretical and empirical insights.

Abstract

We present the results of an extensive review of studies applying integrated food metrics to assess the health and environmental impacts of food, as well as of studies advancing definitions of the components and boundaries of healthy and sustainable food systems and diet. We review the literature in seven identified categories: assessments of health and environmental impacts of common diets, assessments of the environmental implications of shifting to healthier diets and vice-versa, optimization studies, assessments of the effect of following dietary quality indices on the environment, model diets and guiding frameworks, metrics frameworks for integrated food system impact assessments, and metrics frameworks for integrated dietary impact assessments. We critically discuss the approaches to metrics selection, the nature of metrics, the scale at which they operate, data sources, analytical methods, and target audiences. We conclude that there is a need for more holistic and systematic approaches to defining metrics of healthy and environmentally sustainable diets. Based on identified gaps, we propose a set of 10 criteria to guide the development of more integrated and systematic food metrics for human and environmental health in the future.

Introduction

The global food system currently operates unsustainably both in terms of human and planetary health. Agriculture is responsible for up to 30% of global greenhouse gas emissions (GHGe) (Vermeulen et al., 2012) and 70% of freshwater withdrawals. It is the main source of nutrient overload into aquatic and marine systems, a large chemical polluter, and has expanded like no other land use at the expense of biodiverse carbon storing forests, today covering 40% of ice free land on Earth (Foley et al., 2011; Ellis and Ramankutty, 2008). In addition, 85% of global fish stocks are fully exploited or overfished (FAO, 2015; Deutsch et al., 2011). Food production is thus an essential sector to address in order to achieve overall environmental sustainability (Garnett, 2013). Reciprocally, environmental stewardship is a fundamental determinant of food production: a deteriorated resource base with the loss of key ecosystem services such as pollination and climate regulation, will inevitably undermine system productivity, and consequently have severe repercussions on human health and food security (MEA, 2005; Ramankutty et al., 2006; Myers et al., 2013).

The world also faces a “double burden of malnutrition” (Tirado et al., 2010): while nearly 800 million people still go hungry, more than 2 billion are overweight or obese, and this number is growing rapidly (Ng et al., 2014; Black et al., 2013; FAO, 2015). Hunger and undernutrition remain an acute challenge to global health; the FAO (2015) reported an increase in hunger for the first time in two decades. Simultaneously, the growing obesity trends are linked to the increasing burden of non-communicable diseases (NCDs), such as cancer, cardiovascular disease and type II diabetes. NCDs have now surpassed infectious diseases as the world’s fastest-rising public health problem globally and the largest cause of death in absolute terms, accounting for 63% of global annual deaths (WHO, 2011). Unhealthy diets are a key driver of this epidemic, and in 2010, unhealthy diets surpassed smoking as the leading risk factor for disease worldwide (Lim et al., 2012). Underlying these problems are demographic and socio-economic trends driving changes in dietary patterns worldwide, characterized by an increasing demand for animal products and the consumption of low-diversity and low-quality foods.

To address rising global environmental risks, while creating a nutritionally adequate food future for a world of nearly 10 billion, the global food system needs deep transformation. Despite well-documented linkages and feedbacks between factors underlying public health and sustainability in the context of food, the issues of food production, diet, public health, and environmental and climate change have largely been addressed as separate agendas in science, policy and business—an approach that has proven ineffective (Dora et al., 2015; Johnston et al., 2014; Allen et al., 2014). Consequently, an integrated agenda for healthy diets from sustainable food systems is urgently needed across sectors and academic disciplines.

The Transformative Potential of Integrated Food Strategies

A key requirement to achieve transformative change is to identify and promote “win-win” diets and food production practices that meet both health and environmental goals (Riley and Buttriss, 2011; Macdiarmid et al., 2012). The untapped potential is enormous: Springmann et al. (2016) have estimated that transitioning toward more plant-based diets in line with standard dietary guidelines could reduce global mortality by 6–10% and food related GHGe by 29–70% compared with a reference scenario in 2050.

Identifying and promoting “win-win” diets requires quantitative tools that enable a systematic analysis of the complex relationships between the environmental and health effects associated with the ways in which food is produced and consumed (Fanzo et al., 2012; Riley and Buttriss, 2011; Macdiarmid et al., 2012). Integrated food metrics (IFM) are necessary to quantify what a healthy and sustainable diet entails, and thereby to inform the design of effective food and agricultural policies that promote better sourcing among producers and food industries, to mobilize civil society and the investor community, as well as to encourage better eating habits among consumers (Food Forum, 2014; FCRN, 2016).

A vast body of literature has previously proposed metrics spanning food, environment and health, but the majority considers these in siloes and at varying scales (Fig. 1). For example, some metrics focus on sustainable agricultural practices, some on the water footprint of foods, some on dietary diversity, some on the nutritional quality of a diet with regards to a specific nutritional group, some on ecosystem health and yet some on diet-related population health indicators.

In this paper, we review the advancement of metrics for defining and/or assessing the health and environmental impacts of food and diet. We provide a comprehensive map of existing work that has linked health and environmental metrics into composite indicators, indices and rating systems, as well as initiatives on dietary programs, guidelines and principles for sustainable and healthy eating. Through this review, we investigate what aspects of environment and health (and in what constellations) have hitherto been included in dietary assessments and studies proposing quantitative definitions of healthy and sustainable diets. We discuss the strengths and weaknesses of existing metrics, as well as the challenges in developing metrics that are holistic, understandable and applicable in practice.

Methods

We conducted a literature review of studies proposing and/or applying food metrics that combine both health and environmental aspects, as we consider these two domains to be the ‘hard-wired’ components of diet; a sustainable diet must be produced within planetary boundaries of safe resource use (Steffen et al., 2015) at the same time as fulfilling the nutritional requirements of the human body.

The review was conducted through keyword searching in PubMed, Science Direct, Web Of Science and Google Scholar, as well as upon expert literature recommendation. The following search terms were used in multiple combinations: “food”; “diet”; “health”; “nutrition”; “sustainability”; “environment”; “metrics”; “indicators”; “parameters”; “modeling”; “framework”; “analysis”; “impact”; “scenario”; “life cycle assessment.” We included studies that have proposed and/or applied metrics:

- (1) containing one or more indicators;
- (2) spanning both the environmental and health dimensions of food;
- (3) operating at diet level or other levels that are scalable to diet.

We identify and describe seven categories of studies, providing a structured overview of the state-of-the-art in this young transdisciplinary field. The studies cited throughout the review constitute a nonexhaustive set of examples to illustrate the different categories of studies and underlying methodologies that exist in the literature.

Review of Food Studies Integrating Health and Environment

A Growing Demand for Integrated Food Metrics

A legacy of the historical separation of health and environmental issues in the context of food is the persisting lack of integrated dietary guidelines that consider nutrition and environment in tandem (Fig. 2). Still about half of the world’s countries lack national dietary guidelines, and only a few countries have national guidelines that consider both nutrition and the environment: Sweden, the Netherlands, Canada, Qatar and Brazil.

There is, however, a growing realization both within and beyond the research community that an integrated approach to food and diet is paramount to avoid niched strategies that optimize either for environment or health, thereby risking to inflict negative side-effects on one or the other. Integrated strategies toward improving diets would enable to harvest significant economic win-wins which have been estimated to 0.4–13% of global GDP through savings in GHGe and healthcare expenditure (Springmann et al., 2016).

The UN Sustainable Development Goals (SDGs) are an example of the ongoing shift toward a more integrated approach to global sustainability. Notably, out of the 167 proposed SDG targets, about half relate directly to food, which shows how central a theme food is to achieve sustainability overall. Similarly, the UN Standing Committee on Nutrition also recognizes the need for integration, as illustrated in a 2014 technical note on strategies “Towards sustainable, healthy food systems” (Remans et al., 2014). An integrated approach was also recommended by the 2015 United States Dietary Guidelines Advisory Committee, but

Fig. 2 Global outlook on national dietary guidelines. In orange: countries that have national dietary guidelines in place; in white: countries lacking guidelines; in green: countries that have implemented guidelines integrating both nutrition and environment. Data from Food and Agriculture Organization (FAO) (2019) Food-based dietary guidelines. Source: <http://www.fao.org/nutrition/nutrition-education/food-dietary-guidelines/en/>. Accessed on 2 January 2019.; Gonzalez-Fischer, C., Garnett, T. (2016). Planets, pyramids and the planet: Developments in national healthy and sustainable dietary guidelines: A state of play assessment. Food Climate Research Network (FAO) and Food and Agriculture Organisation (FAO).

was subsequently censored by Congress, which passed a law prohibiting dietary guidelines to mention environmental impacts after intense lobbying from the meat and dairy industry.

A significant number of recent academic studies have also promoted the need for more holistic and standardized assessments of the impacts of diet on health and environment (e.g. Jones et al., 2016; Auestad and Fulgoni, 2015; Demaio and Rockström, 2015; Herforth et al., 2014; Johnston et al., 2014; Allen et al., 2014; Garnett, 2013; Macdiarmid, 2013). They point to the critical need to identify research gaps, clarify and harmonize definitions and concepts, set research priorities, and systematically examine trade-offs.

Studies Proposing and Applying Integrated Food Metrics

In recent years, there has been an upsurge of scientific literature advancing IFM to assess the impacts of food on both health and environment (e.g. Lukas et al., 2015; Tilman and Clark, 2014; Johnston et al., 2014; Allen et al., 2014; Heller et al., 2013). A review by Auestad and Fulgoni (2015) of the sustainable diets literature found that two-thirds of the captured studies were published 2010–2014.

Below we provide a detailed examination of the studies identified in our review of food metrics specifically interlinking health and environment. We identify seven categories of studies based on the diverging ways in which environment and health considerations have been integrated and costudied.

Assessments of health and environmental impacts of common diets

Many studies assess the health and environmental outcomes of common dietary patterns and food groups. These are considered ‘static’ in the analysis, in contrast with scenario-based studies that assume dietary shifts (described below). For example, Van Dooren et al. (2014) compare six dietary patterns in terms of GHGe, land use and 10 nutritional indicators. Tilman and Clark (2014) present a comparative assessment of three global dietary patterns—Mediterranean, pescetarian and vegetarian—against current and future global average diets under a business-as-usual trajectory with regards to GHGe, land-use change and three health outcomes (diabetes, cancer, cardiovascular disease). The combined impacts of diet on climate change and mortality from chronic disease are studied in Scarborough et al. (2012). The land use dimension is added in a similar analysis by Biesbroek et al. (2014). A different health angle is adopted by Rööfs et al. (2015) who assess the adequacy of dietary nutrients alongside GHGe, land use and biodiversity impacts. Similar studies have been conducted on specific food groups, e.g. Aston et al. (2012) or Temme et al. (2013) who assess the combined impacts of consuming red and processed meat.

These studies often consider a narrow set of indicators. In the review by Auestad and Fulgoni (2015), only two studies were found that considered multiple indicators of health and environment. One of them examined the impacts of four dietary patterns using 11 indicators then aggregated to a single score, and the other compared the impacts of habitual diets in the EU27, those recommended by the WHO and the WCRF, and the Mediterranean diet across eight impact categories (Baroni et al., 2007; Wolf et al., 2011).

Assessments of the environmental implications of shifting to healthier diets, and vice-versa

A substantial body of literature investigates the environmental implications of shifting to healthier diets. Heller et al. (2013) have suggested that a dietary shift from the average US diet to national dietary recommendations could lead to a 12% decrease in diet-related GHGe. Hendrie et al. (2014) have demonstrated that red meat and energy dense nutrient poor “non-core” foods are the largest contributors to diet-related GHGe in the average Australian diet. Similarly, Fazeni and Steinmuller (2011) have shown that decreasing meat consumption by 60% and increasing fruit and vegetable consumption as recommended by the German Nutrition Society for Austria would lead to lower energy demand and GHGe, while increasing the availability of land for other forms of production. Macdiarmid et al. (2012) designed a diet including 52 food items, which would meet UK dietary requirements for adult women as well as lead to a 36% decrease in GHGe.

A common problem across these methodologies is that they are health driven, and thus adopt a narrow approach to environmental sustainability, usually only considering GHGe. A limited number of studies concentrate on other environmental variables such as water use (e.g. Hess et al., 2015), land use (e.g. Peters et al., 2016) and nutrient loading (e.g. Westhoek et al., 2014). Only some studies consider several variables combined, such as Behrens et al. (2017) who quantified the impacts on GHGe, eutrophication and land use of adopting nation-specific Nationally Recommended Diets compared with national average diets in 37 countries, showing significant impact reductions in high-income countries but significant increases in lower-middle-income countries.

Some studies have also assessed the environmental implications of reducing specific health risks rather than all-cause mortality, e.g. Downs and Fanzo (2015) examined the carbon, water and ecological footprints of the components of a cardio-protective diet.

The reverse analysis—assessments of the health implications of shifting to environmentally sustainable diets—is far less common. A systematic review by Alexandrowicz et al. (2016) identified 210 diet studies considering GHGe, land use and/or water use, of which only seven reported on health effects, e.g. Milner et al. (2015) who examined the effects on NCD mortality of low-GHGe diets. Alexandrowicz et al. (2016) identified 14 sustainable dietary patterns with reductions of up to 70–80% in GHGe and land use, and 50% in water use compared to baseline diets, for which they also found evidence for reduced risks (albeit modest) of all-cause mortality.

A multi-perspective study by Springmann et al. (2018a) assessed the effects of three dietary-change strategies (environmentally, food security and health driven) on premature mortality, nutritional adequacy and environmental impacts in 150 countries, demonstrating important trade-offs in the two former strategies while the health driven strategy led to the greatest benefits overall.

Optimization studies

A rarer body of work has attempted to optimize the health and environmental outcomes of diet, often adding an economic perspective to the analysis. These studies are using computing methods such as linear programming to optimize the mix of foods to meet specific nutritional and environmental criteria. For example, Wilson et al. (2013) considered the adequacy of dietary nutrients alongside GHGe. A more holistic analysis was provided by Masset et al. (2014) who considered GHGe, nutritional adequacy, energy density and cost.

Assessments of the effect of dietary quality indices on the environment

Some studies have investigated the environmental implications of using different dietary quality indices. For example, Kägi et al. (2012) compared different measures of diet quality to study the relative environmental impacts of different restaurant meals, concluding that using a Nutrient Density Score emphasized vegetable contributions to the diet and hence reduced the environmental impact differences between meals, while using the Nutrient Richness Food Index emphasized meat contributions to the diet, hence highlighting differences. This shows the importance of choosing the appropriate unit of assessment or comparing different ones. Similarly, van Kernebeek et al. (2014) compared the GHGe of different diets using a diet-level nutrient profiling scheme, and suggested that when using nutrient-based criteria, nutrient levels should be capped at 100% of the recommended daily value to prevent “crediting” overconsumption. Vieux et al. (2013) studied the GHGe of French diets while taking into account three measures of nutritional quality: Mean Adequacy Ratio above the median, Mean Excess Ratio below the median, and energy density below the median. They concluded that diets with higher nutritional quality are associated with higher GHGe. These results contradict the broad conclusion in the literature that healthy diets, rich in fruits and vegetables, are also more environmentally sustainable than unhealthy diets. However, this may be explained by the high energy density and relatively low GHGe of low-nutrition foods (in addition to their ease of transport and storage, and low risk of wastage).

Model diets and guiding frameworks

Another set of studies propose ‘model’ diets and guiding frameworks to help consumers improve their nutrition while limiting environmental impacts. Various ideal plates have been suggested, such as the Menus of Change designed by the Harvard School of Public Health in collaboration with the Culinary Institute of America (2014). Other creative forms of outlining healthy and sustainable diets include dietary programs, food score cards and food pyramids, such as the Barilla Centre For Food and Nutrition’s Double Pyramid (2009), which displays foods along health and sustainability gradients. The LiveWell for LIFE initiative outlines a diet that is both healthy and minimizes environmental impacts, taking into account GHGe, obesity prevalence and economic spillovers (WWF-UK, 2012). The FAO has suggested the Mediterranean diet as a prime example of a sustainable diet that takes into account nutrition, biodiversity, local food production and culture (Burlingame and Dernini, 2011), but a challenge is that the Mediterranean diet definition varies between studies (Bach-Faig et al., 2011).

Similarly, a few countries have developed national dietary guidelines that consider both health and environment (Fig. 2). These include emphasizing a plant-based diet, reducing leftovers and waste, consuming locally and regionally produced foods when available, choosing fresh and homemade foods over highly processed and fast foods, conserving water and energy in food preparation, and enjoying meals in good company (Seed, 2014; Brugård Konde et al., 2015; Kromhout et al., 2016; Monteiro et al., 2015).

Metrics frameworks for integrated food system impact assessments

The sparsest set of studies are those that present novel quantitative frameworks for integrated assessment of health and environmental impacts of food systems and diet. Remans et al. (2014) have proposed 10 core principles with associated metrics for measuring the nutritional adequacy and environmental sustainability of food systems. An Institute Of Medicine (IOM) and National Research Council (NRC) (2015) report has advanced an integrated framework for assessing the total impacts of policies across sectors (health, environment and agriculture) in order to equip decision-makers with a tool that enables to test policies for potential negative side-effects on other sectors. A framework has been advanced by Gustafson et al. (2016) to compare the performance of different countries' food systems, employing 25 sustainability indicators across seven domains—nutrition, environment, food affordability and availability, sociocultural well-being, resilience, food safety, and waste. Based on the latter, Chaudary et al. (2018) presented a global-scale analysis quantifying the national food system performance of 156 countries, showing very different patterns of performance between countries. Prosperi et al. (2014) have proposed a food system vulnerability framework comprising 12 indicators measuring exposure, sensitivity, and adaptive capacity of the Mediterranean food system, including nutritional and environmental considerations. A Delphi process was conducted by Allen et al. (2014) to determine a set of key metrics for sustainable food systems, which yielded 15 indicators spanning sustainable production, economic vulnerability and adequate nutrition. Further, Conijn et al. (2018) used the planetary boundaries for land system change, climate change and biogeochemical cycles as benchmarks for analyzing whether different interventions could meet global food demand within planetary boundaries by 2050, showing that shifting to healthier diets (replacing 50% of meat consumption by plants) has a major role to play, but needs to be complemented by significant waste reductions and drastically improved production practices.

A recent report by the EAT-Lancet Commission on Food, Planet, Health (Willett et al., 2019) proposes a “planetarsy health diet” defined by food group-based consumption brackets that together provide the span of a healthy diet, coupled with a quantitative definition of sustainable food production systems based on impact boundaries for water, land, and nutrient use, as well as GHGe and biodiversity loss. The report, as well as a spin-off analysis by Springmann et al. (2018b), confirm the findings of Conijn et al. (2018). The advancement of a comprehensive set of quantitative benchmarks for sustainable food systems is a key contribution of this report, as previously proposed model diets and guidelines were of a broader, qualitative nature and thus lacked the granularity to guide food system actors toward the necessary changes. However, the EAT-Lancet report does not consider environmental impacts postfarmgate, and assumes a decarbonized food system by 2050, making the needed food system changes even greater than the report states. Further, the environmental benchmarks are set at global food system level, causing a scale discrepancy with the health boundaries (set at diet level) and would require downscaling to diet in a regionally adapted manner.

Metrics frameworks for integrated dietary impact assessments

Only a few studies have proposed integrated metrics frameworks that are readily applicable for quantitative dietary assessments. Lukas et al. (2015) introduced the Nutritional Footprint comprising four environmental and four nutritional indicators, and show-cased the framework through a range of meal comparisons. Heller et al. (2013) proposed a conceptual framework for diet-level integration of environmental impacts and nutritional quality assessment which includes a combination of assessment methods, and examples of mid- and end-point indicators. Johnston et al. (2014) offer a descriptive analysis of the determinants of sustainable diets and present a qualitative framework of components and underlying factors and processes to frame what constitutes a holistically sustainable diet. A matrix was proposed by Van Dooren et al. (2014), collapsing land use and GHGe into an environmental axis and 10 nutrient indicators into a health axis, which enables to plot diets and food components against both health and sustainability. Smedman et al. (2010) estimated a composite nutrient density, expressed as percentage of Nordic Nutrition Recommendations for 21 essential nutrients, in relation to cost in GHGe of the production from a life cycle perspective, using an index called the Nutrient Density to Climate Impact index (NDCI). The European project SUSFANS, launched in 2015, is also advancing a definition of ‘SHARP’ diets (Sustainable, Healthy, Affordable, Reliable and Preferred), incorporating metrics of nutrition, environment, economics and food security(SUSFANS, 2017).

A Critique of Existing Food Metrics

As illustrated in this review, a myriad food metrics, guidelines and principles have previously been proposed and applied to various aspects of health and environment, relating to different parts of the food system. This fragmented landscape of metrics demonstrates how diverse food systems analysis is, and at the same time how disconnected studies are. This knowledge can easily be perceived by non-experts as overwhelming. Below we discuss some of the main challenges and gaps associated with previous attempts at developing IFM.

Adopting a Systems Approach to Developing Food Metrics Frameworks

There is an increasing trend toward integrating health and environmental metrics. Still among these more integrated frameworks, there are aspects of health and environment that are rarely represented. A systematic review of studies addressing the measurement of sustainable diets conducted by Jones et al. (2016) identified 30 different metrics of sustainability, among which most studies have evaluated GHGe and to some extent also water and land use, while biodiversity impacts, the disturbance of biogeochemical flows, antibiotics and pesticide use, food waste, and animal welfare are key neglected areas. This pattern of dominance of studies focusing on GHGe was confirmed in the review by Alexandrowicz et al. (2016) as well as in our review. More broadly, metrics related to food production have hitherto favored land-based systems, though productive and extractive marine and freshwater systems are equally important. The great majority of studies are also located in the Global North.

Adopting a systems perspective is essential to identify not only the synergies but also the possible trade-offs between health and environmental goals in the context of food production and diet, which previous studies have already demonstrated exist (Drewnowski, 2014; Ingram, 2011; Macdiarmid, 2013). Hence the importance of food studies encompassing a comprehensive set of metrics. A research priority for studies applying IFM should be to identify scenarios in which sustainable food production aligns with suggested standards for healthy diets similar to the analyses run by the EAT-Lancet Commission (Willett et al., 2019) but at regional scales, for example: how and where could the current under-production of nuts, seeds, fruits and vegetables be carried out so as to minimize environmental impacts? Ironically, foods associated with a healthy diet (e.g. fruits, vegetables and nuts) are to a large extent currently sourced from production systems with low resilience.

Though environmental impacts of food overall are mainly generated at the production stage, that may vary depending on the type of food and supply-chain considered (Viola and Marinelli, 2016). The healthiness of a food is also largely determined by its processing. Diet studies should thus increasingly consider the whole life-cycle of foods, including their preparation. Currently, environmental impact measurements tend to be limited to farmgate and the nutritional quality of foods tends to be evaluated based on their raw form. Ingram (2011) has argued that food metrics should reflect a shift from “what we get” (i.e. the outcomes of food system activities, such as food access and food stability) toward “what we do” (i.e. the activities, such as producing and processing).

Harmonizing Language and Methodology

Not only do the metrics considered vary greatly between studies, the functional units, terminologies, methods and data sources also vary, rendering these studies difficult to compare (Jones et al., 2016; Auestad and Fulgoni, 2015; Hallström et al., 2014). Many authors in the field are calling for streamlined methodologies, as a strong scientific foundation of comparable high-quality studies would support progress in advancing healthy and environmentally sustainable diets.

With regards to functional units, Lukas et al. (2015) base their dietary calculations on *dishes*, whereas Tilman and Clark (2014) construct long-term *dietary patterns* (e.g. Mediterranean or vegetarian) based on meta-data, and Gustafson et al. (2016) make comparisons between *country average diets*. These all differ with regards to time and scale. Each of these approaches has limitations; on the one hand, studying dishes enables a greater level of specificity and accuracy than dietary patterns which require building in a range of assumptions in terms of the foods consumed but on the other hand, studying dietary patterns is more representative of a person's dietary habits than a single dish. Other examples of inconsistency are the discrepancies between studies considering nutritional requirements (e.g. Lukas et al., 2015) versus those considering health outcomes (e.g. Tilman and Clark, 2014), or between studies considering specific health aspects (e.g. Downs and Fanzo, 2015) versus those considering total health (e.g. Springmann et al., 2018a). Beyond the scope of this review are also studies considering specific food groups or products in contrast to studies considering the whole diet.

Studies also demonstrate variations in terminologies used to link food and environment, such as “diet,” “food system,” “value-chain,” “farming,” “agriculture,” or “food consumption” (Auestad and Fulgoni, 2015). The definitional boundaries between these terms is sometimes unclear, for example whether “sustainable diet” considers the sustainability of the whole underlying food system or not. The definition of typical diets such as “Mediterranean” or “vegetarian” diets also vary in terms of the assumed food content and balance.

The approach to selecting metrics in existing IFM frameworks is often poorly specified. More robust, explicit methods for metrics selection will be important in the future, in order to justify why some metrics are included while others are excluded. Criteria for selection could be, for example, data availability, frequency of use in previous studies, importance of the issue represented (in terms of magnitude of current impact), and actionability.

Studies rarely advance or adopt a quantitative definition of a healthy and sustainable diet (Harray et al., 2015), meaning that dietary impact levels are measured but not benchmarked against clearly defined sustainability and health levels. The growing field of dietary assessments based on IFM should look to systematically compare dietary impacts against a standardized set of benchmarks, such as those advanced in the EAT-Lancet Commission (Willett et al., 2019). The FAO (2012) has also advanced an official qualitative definition of sustainable diets, which could provide a good basis for translation into quantitative benchmarks.

Lastly, the data used in previous dietary assessments also vary broadly. On environmental impacts, some studies use primary LCI data, some use secondary LCA data from different platforms such as Agribalyse and Agrifood, and some use non-LCA data describing food impacts at farm-gate (often footprint data). Extensive debate among the scientific community has occurred around the relative strengths and weaknesses of footprinting versus LCA (Hoekstra, 2016; Pfister et al., 2017). Both methods carry the limitation that multiple definitions and system boundaries are used. In the case of LCAs, these sometimes only consider cradle-to-farm

gate impacts whereas others will consider cradle-to-grave impacts (Weidema et al., 2008). LCAs also vary in terms of the functional unit used, characterization factors (coefficients used for converting between units of measurement), and allocation factors (how environmental impacts are being allocated in mixed production systems). This inconsistency makes studies difficult to compare or aggregate, particularly when methods are not thoroughly described (Hallström et al., 2014). LCA data is therefore more useful for comparing the impacts of very different foods or diets, rather than similar ones (i.e. marginal impacts). Cucurachi et al. (2016) mention as a key challenge the fact that LCA tools to quantify marginal impacts are still evolving, and call for a protocol for mining data from diet LCA studies considering completeness, system boundaries and underlying assumptions.

On nutritional intake, data sources vary from clinical trials, 24 h recall surveys, case-control studies, cohort studies, to national nutrition composition tables. Data platforms vary from direct collection, to UN-hosted or other global databases such as FAO, WHO, World Bank, to national health agencies, models and meta-analyses.

Generating and Accessing the Necessary Data

An acute barrier to applying IFM in dietary assessments is the current limitation of data on foodstuffs from specific production systems. A comprehensive body of open-access food environmental data is currently hosted by international organizations such as WHO, FAO and the World Bank, but the data only represents impacts at farmgate and fails to distinguish impact levels based on production practices. The food industry has hitherto been skeptical to disclosing internal supply-chain data. LCA-based data can be found in the literature but is scattered.

Many environmental indicators related to food production also have strong spatial and temporal dependencies, e.g. fluctuations in yield between seasons and regions, which are often not captured in impact studies. Acknowledging these dependencies requires high-resolution datasets and more sophisticated impact assessment methods than used today, for instance basing yield estimates on longer time-series than just one season. In a study of rice farming in Bangladesh, Henriksson et al. (2014) showed substantial variation in environmental impacts between the two to three different farming seasons which are each associated with their own sets of farming practices, intensities of irrigation and yields. Similarly, given that the majority of metrics currently in use for measuring “nutritional quality” rely on a cultural norm by considering food groups, metrics may need to be adapted to local to regional scales. More absolute measures of ecological “nutritional health” that are strongly rooted in epidemiology and applicable universally to human diet are therefore desirable (Heller et al., 2013).

Toward Better Design Criteria for Integrated Food Metrics Frameworks

Drawing from our review, we propose a set of 10 key criteria for future studies advancing IFM frameworks for environmentally sustainable and healthy diets.

1. *Scope*—The framework should represent a holistic set of environmental aspects that, together, regulate the stability of the Earth system, and of nutritional requirements that ensure human health and wellbeing.
2. *Thresholds*—The indicators should carry quantitative thresholds that reflect a sustainable environmental impact and adequate intake for good health. Environmental thresholds should be adapted to the regional context and ecology from which the diet is sourced.
3. *Scientific credibility*—The framework should reflect the scientific evidence on key environmental and nutritional requirements for Earth system stability and good health. The scientific motivations behind the selection of each specific indicator should be specified.
4. *Time scale*—The framework should principally be designed for assessing dietary patterns rather than individual meals, as meals may not be representative of long-term consumption habits. However, meal-based analyses allow for deeper analysis of environmental impacts (see criterion 6 below).
5. *Spatial scale*—The framework should carry flexibility with regards to scale of analysis, given that food consumption data can be gathered at individual, country, regional or global level. Depending on the scale of interest, impact measures could be converted from national-to-global averages down to per-capita measures, and vice-versa.
6. *Life-cycle stages*—Analyses beyond farm gate require detailed information on food’s origins, processing and transport, which is nearly impossible to account for in assessments of longer-term dietary patterns, in addition to post-farm gate data on many highly processed foods being limited. However, if analyzing particular foods where post-farm gate impacts are known to be significant, e.g. fruits and vegetables, these may be important to include.
7. *Production practices*—The framework should, if possible, include a component that captures the production context of food (production mode, animal welfare, embedded ecosystem sensitivity and value) as an ‘add-on’ to the core framework that would be relevant particularly for detailed diet analyses, e.g. individual meals, as it requires detailed information on each food component. Studying production system properties could also be useful in broader food system analyses.
8. *Data sourcing*—For environmental impacts, we recommend the use of footprint or LCA data from peer-reviewed studies that have clearly defined methodologies and use the same system boundaries, allocation factors and characterization factors for comparability. For nutritional intake, we recommend using food nutrition composition tables from governmental agencies or reliable academic sources. For consumption data, we recommend using (sub-)national food surveys from national authorities

Fig. 3 Prototype of an integrated food metrics framework applied to a fictive diet.

or the peer reviewed literature, or aggregated global data from international organizations (e.g. the United Nations or World Bank), though the scale of interest will to a large extent determine the data source.

9. *Aggregation of results*—It would be useful to develop a method that allows to collapse the framework metrics into a single index or score. This would be useful in making comparisons between, e.g., countries or common dietary patterns.
10. *Practical applicability*—The framework should be designed with the aim to be useful in practice, which requires wrapping a complex set of metrics into a simply communicated message without losing critical information on the way.

Building on previous studies and gaps identified in our literature review, we propose a conceptual prototype for an IFM framework in Fig. 3 to which we have applied a fictive dietary assessment. The blue dots represent health indicators; the orange dots represent environmental indicators. The circular area in green delimits the ‘plate boundaries’ within which impacts on health and environment are considered adequate. The area in orange delimits the ‘risk’ zone, which represents the scientific uncertainty range as well as nutritional flexibility with regards to health effects of food and nutrient intakes. The red zone going outwards is the ‘danger zone’ where impacts on health and environment are scientifically asserted to be harmful. The radial distance from the central black dot to each indicator represents the level of impact measured by each indicator. The fictive diet we plotted falls outside of all plate boundaries except for one health indicator. The area delimited by the black line connecting all indicator levels is used to illustrate a diet’s total dietary impact; this area could also be used to calculate total impacts.

Radial plots have also been used in previous studies (e.g. Lukas et al., 2015; Gustafson et al., 2016) as these enable to easily visualize trade-offs between indicators and identify diets that score within plate boundaries. Represented in this way, results may also become more easily interpretable by non-expert audiences.

Conclusions

The scientific literature contains a wide and fast-growing array of metrics that assess the health and environmental impacts of food. However, most previous studies advancing IFM consider only a few indicators, and thus fail to adopt a systems perspective where health and environmental aspects are interlinked and compared. This puts dietary evaluations at risk of failing to detect potential trade-offs between different environmental and health considerations, or to identify important added benefits.

Some aspects of health and environment have hitherto been well represented by metrics whereas others, although of similar relevance, are frequently neglected. Methodologies, data sources and terminology also vary widely between studies, rendering comparisons of their results difficult.

Future research should seek to consolidate, harmonize and complement existing metrics in order to move toward integrated frameworks that consider a wide range of key health and environmental aspects, that provide quantitative benchmarks for environmentally sustainable and healthy levels of impact, and that are practically useful to food system actors with regards to food choices, production practices or sourcing standards.

We present a prototype for an IFM framework that would allow to conduct absolute assessments of diets’ nutritional adequacy and environmental sustainability, as well as to identify potential trade-offs between objectives. Possible future research applications of such a framework could be, for instance, to assess the environmental implications of shifting food production practices to meet guidelines for healthy diets.

Acknowledgments

We wish to extend our thanks to our colleagues Malin Jonell, Patrik Henriksson, Max Troell and Sarah Cornell at Stockholm Resilience Centre for providing extensive comments and novel perspectives to this paper during the course of its development. Our thanks also go to colleagues at the EAT Foundation for their continuous support to this work.

Abstract

Water management is increasingly challenged by climate and technological changes, socioeconomic trends, and aging infrastructure, among myriad others challenges. The traditional top-down, fragmented approach to water management is insufficient to address these challenges. Integrated water resource management, a collaborative and holistic approach, is critical to successful water management. The involvement of those who excel in multi-sector and diverse stakeholder collaboration are required. Boundary spanners are individuals within an organization who can reach across organizational borders to build relationships, interconnections, and interdependencies in order to manage complex problems. Although these individuals may operate on the edge or periphery of an organization, they position themselves as both internal and external communicators. Boundary spanners actively work toward collaboration, attempting to link diverse stakeholders, processes, and information from multiple perspectives in order to influence policies and practices and increase social learning between stakeholders. The multilevel nature of boundary spanning aids the movement and acknowledgement of ideas across various sectors, organizational or geographic boundaries, and political alliances. This article describes the need for, and incorporation of, boundary spanners in integrated water resource management.

Introduction

Water management is increasingly challenged due to changes in availability of water in both quantity and quality. The challenges are being driven by climate change with increasing temperatures and more extreme weather events, rising demand as a result of population growth and other demographic changes (e.g., urbanization), and agricultural and industrial expansion among myriad other drivers. The traditional top-down, fragmented approach to water management is no longer viable. Most water quantity and quality problems are the result of human activity (Rockström et al., 2014; Schultz, 2011); and thus it is more often their social complexity, not their technical complexity, that confront water management. A more holistic, multi-disciplinary, participatory approach is essential. The integrated water resources management (IWRM) approach is considered a preferred way forward “for efficient, equitable and sustainable development and management of the world’s limited water resources and for coping with conflicting demands” (UNDESA, 2014). IWRM is defined as “a process which promotes the coordinated development and management of water, land and related resources, in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems” (Hassing et al., 2009, p.3). Introducing boundary spanners into the IWRM process supports collaborative efforts and aids in the development of trust as well as knowledge and perspective sharing while setting the stage for more productive outcomes and future collaboration between parties.

Boundary Spanners

Boundary spanners are individuals within an organization who can reach across organizational borders to build relationships, interconnections, and interdependencies in order to manage complex problems (Williams, 2002). Boundary spanners “manage out,” or across, social and professional ties to influence policies and practices (Austin, 2002; Cash et al., 2006; Klein, 1996). According to

Zhao and Anand (2013), boundary spanners operate on the edge or periphery of an organization positioning themselves as both internal and external communicators. Although boundary spanners typically represent their home organizations, they actively work toward collaboration, attempting to link diverse stakeholders, processes, and information from multiple perspectives (Alexander et al., 2016; van Meerkkerk and Edelenbos, 2014). As representatives of their home organizations boundary spanners operate informally within collaborative endeavors (Safford et al., 2017). By acting as inter-organizational ambassadors, they have an opportunity to influence perceptions and improve knowledge sharing between stakeholders. Creating multiple pathways for stakeholders to learn about each other's values, experiences, and skills is critical to positive collaborative outcomes (Coleman and Stern, 2018).

History of Boundary Spanning

The idea that information exchange from external areas was crucial to continued business development and innovation emerged in the mid-20th century; yet the literature at the time suggested that communication across different spheres within organizational boundaries was not only inefficient, but open to bias and misrepresentation (Dearborn and Simon, 1958; March and Simon, 1958; Wilensky, 1967). Thus, early research on how to manage boundary complexities emphasized the role and development of *gatekeepers* specifically in the area of technology transfer between different departments of an organization (Aldrich and Herker, 1977; Tushman, 1977; Tushman and Scanlan, 1981; Friedman and Podolny, 1992). The notion that boundary spanning could aid the process of innovation by linking an organization's internal network to external sources of information encouraged further investigation as to the usefulness of boundary spanning beyond external information transfer. As institutions and corporations continue to grow in size, they differentiate into specialized areas, each working with specialized tasks or environments. These specialized units develop their own norms, processes, language, and coding schemes, which have the potential to hamper information exchange. Communication across organizational boundaries becomes more and more difficult, thereby harming future development and innovation as well as team cohesiveness. The idea of identifying individuals who have the ability to span networks and encourage knowledge sharing became increasingly important.

Friend et al. (1974) identified a cluster of networking skills as an important characteristic of boundary spanning work and encouraged the development of certain interpersonal relationships, communication, and political skills while also recognizing the interconnectedness of problems and their potential solutions. Webb (1991) refers to certain individuals who possess particular skills within an organization or collaborative effort as those "who are especially sensitive to and skilled in bridging interests, professions and organizations" (p. 231), while Degeling (1995) views these spanners as "entrepreneurs of power" who understand connections, interdependencies, and fractures between stakeholders (Williams, 2002, p. 109). Gradually, the notion that there exists "special" individuals who possess the innate ability to bring people together, break through red tape, and observe the situation in a different way found its way beyond earlier and more simplistic explanations of boundary spanning.

Contemporary Boundary Spanning

Boundary spanning is no longer solely reserved for information transfer within business and political sectors. Individuals who possess interpersonal skills, contextual knowledge, and the ability to unite disparate groups around a common goal are now actively engaged in higher education (Miller, 2008; Pryor and Henley, 2018), public relations (Neill, 2014), social media (Van Osch and Steinfeld, 2016), and healthcare related-fields (Long et al., 2013; Wallace et al., 2018).

Moreover, boundary spanners have been found to play a positive role in both internal and external relationships. Neill (2014) found that internal boundary spanning at the division level of an organization increased informal coalitions. Neill concluded that gathering information across departments can lead to not only improved employee relations, but also better strategic decisions at the administrative level. These findings are similar to boundary spanning involvement in higher education. According to Pryor and Henley (2018), the need for boundary spanners is intensifying as higher education becomes increasingly more complex and dynamic. Leadership both horizontally and vertically is required to strategize new responses to complex external challenges. Those in higher education are seeking individuals who have the ability to manage boundaries, forge common ground, and model collaboration. Pryor and Henley determined that institutions of higher learning are replete with departmental silos and, thus the challenges of building inter-disciplinary alliances and minimizing traditional hierarchical arrangements are critical to opening up effective channels of communication. This is consistent with other research (Floyd and Fung, 2017; Kok and McDonald, 2017) indicating that internal boundaries can reduce inter-organizational coordination interfering with knowledge sharing, innovation, and trust. Thus, a boundary spanner can positively impact relationships with stakeholders external to the organization by improving communication within their home organization.

As the healthcare sector becomes more fragmented, community boundary spanners are being used to connect disparate groups in hopes of improving the flow of information between communities (Long et al., 2013; Wallace et al., 2018). The key challenge is to reduce health disparities by improving relationships across organizations and socio-economic boundaries. Boundary spanning has the potential to facilitate the transfer of specialized knowledge or resources and remove structural holes or barriers that have the potential to isolate communities reducing access to appropriate medical care.

The idea of using boundary spanners to provide effective leadership within a community-based context gained momentum after a 2008 study by Miller focusing on exceptional leadership within university-school-community partnerships. Miller concluded that

individuals with contextual knowledge, interpersonal skills, and high levels of trust could successfully connect dissimilar groups within a community. Furthermore, loyalty to the community and a desire to share knowledge and advocate for those who have been traditionally marginalized increased one's ability to effectively communicate, problem-solve, and increase stakeholder collaboration.

Utilizing boundary spanning as one method of developing informal leadership is valuable to organizations in both Western and Eastern cultures. The evolution of leadership in today's interdependent world requires respect, connection building, intersection of group boundaries, and collaboration toward a common vision. Liu et al. (2018) examined how boundary spanning behavior impacts task performance when mediated by the emergence of informal leadership and hierarchical power inequality (power distance). They discovered that individual boundary spanning is not only an important predictor of leadership emergence, but is positively associated with task performance. In addition, the study revealed that power distance moderates the effects of boundary spanning and has the potential to weaken a boundary spanner's position as an informal leader. Power distance refers to an individual's ability to accept inequality in power; low power distance means individuals expect equality in power and do not accept a leader's authority just because of the leader's position. Researchers have revealed that using boundary spanning activities to improve cooperation, knowledge sharing, and trust between teams at varying levels within an organization increases the likelihood that information exchange across external borders will occur, resulting in better team performance (Choi, 2002; Marrone, 2004). A study done by Liu et al. (2018) demonstrated the multilevel nature of boundary spanning and its usefulness to organizational teams by increasing opportunities to cultivate and improve social networks not only between peers, but also with external stakeholders in order to gather knowledge, share information, and solve problems.

Building Trust Between Stakeholders

Research has found that boundary spanners originate more frequently from private and societal organizations and less from governmental agencies (van Meerkerk and Edelenbos, 2014). The challenge for a government agent acting as a boundary spanner is great, especially when the issue at hand involves numerous scales of governance. Typically, boundary spanners representing public agencies have limited autonomy, which many participants see as undesirable. Studies show that the higher the autonomy of a boundary spanner the more likely she is to develop trust between stakeholders (Williams, 2002; van Meerkerk and Edelenbos, 2014; Thompson et al., 2016). This area, comparing the boundary spanning capacity between private and public actors, however, requires much more study.

Ultimately, boundary spanners attempt to build trust in order to establish solid relationships and improve collaboration between diverse stakeholders. Many are highly sensitive to and skilled in bridging interests and organizations. Numerous studies have shown that trust increases between stakeholders as they participate in the collaborative process (Ostrom, 2003; Davenport et al., 2007; Stern, 2008; van Meerkerk and Edelenbos, 2014). Furthermore, trust has been shown to develop in informal network structures (Edelenbos and van Meerkerk, 2015), and boundary spanners are crucial to creating spaces of interaction so that collaboration can occur. A study done by Coleman and Stern (2018) on three-forest landscape restoration collaborative demonstrated the advantages to using a boundary spanner to help stakeholders agree to rules and procedures, which created a safe place for discussion. This structure allowed participants to express their views and concerns within the participatory process. One boundary spanner from Collaborative A commented, "I like structure; people can trust that they're safeguarded, that there's venues to be heard, there's processes that are supported by the group, whether we like what someone might want to discuss or not, there's a freedom in the structure to allow for, like, a group, like a joint fact finding on an issue if there is a disagreement about it, and we can trust that will happen" (Coleman and Stern, 2018, p. 7).

Increasing Social Learning Capacity

Austin (2002) showed that much of a boundary spanner's work is focused on community practices; that is, on external relations between the organization and its community and on balancing those with internal demands. Boundary spanners devote time to building inter-organizational relationships, as well as pay attention to external issues, build community partnerships, and cultivate a learning organization culture. They create multiple pathways for a community to learn about each other's values, experiences, and skills (Alexander et al., 2016; Coleman and Stern, 2018; van Meerkerk and Edelenbos, 2014). Boundary spanners are critical to "social learning systems" by creating and enacting novel structures of social interaction (Kerson, 2002; Wenger, 2000). Thus, increased social learning ought to enrich the capabilities of IWRM participants.

Power Imbalances

Imbalances of power within the participatory process can leave a boundary spanner struggling to retain and/or engage stakeholders. Stakeholders who feel inadequate because of power or resource imbalances often complain of feelings of exclusion, inequality, and hierarchies. Alexander et al. (2016) revealed that people in governance networks involved with community-based conservation initiatives had to be cognizant of powerful or more influential stakeholders who attempted to control the types and sources of

knowledge. Stakeholders that are more powerful can manipulate social learning and affect the level of trust and collaboration that is formed, thus undermining the participatory process. In these instances, it is critical that boundary spanners find strategies to defuse those behaviors and outcomes. Identifying the core values and interests of a diverse group of stakeholders can be achieved with time (Pretty, 2003); however, key actors need to create the space required for these differences to be deliberated (Lejano et al., 2013; Alexander et al., 2016). Wald et al. (2017) maintain that egocentric behavior within the participatory process of natural resource management must be overcome to establish trust and collaborative behavior.

When control of resources or access is unequal, interventions must occur or those participants with less power will reduce perspective taking and turn away from further collaboration. Previous studies suggest that perspective taking is a key to shared understanding, social bonds, and collaborative behavior (Cialdini et al., 1997), and if stakeholders are unable to develop secure relationships, the collaborative process is at risk. Imbalances exist with not only power or resources, but also ability (Ansell and Gash, 2008). Local stakeholders may not have the skill or expertise to engage in complex or highly technical decision-making deliberations (Yang and Pandey, 2011).

One example of a perceived imbalance of power in the United States occurred during the Platte River Collaborative Watershed Planning Process. Conservation advocates complained that the negotiating table was “uneven and weighted toward development interests” (Ansell and Gash, 2008, p. 551). Since development interests and environmental advocates can have widely diverse capabilities, the collaborative process often favors well-organized and more powerful interests. Some stakeholder groups are spread out and lack the necessary organizational infrastructure placing them at a disadvantage.

Scale Mismatch

Boundary spanners can help overcome inevitable challenges to participants in IWRM related to difference scales of governance and geography. Scale of governance mismatch, experience of the facilitator or project manager, prior conflict between stakeholders, and degree of autonomy of the boundary spanner can add both positive and negative dimensions to the collaborative process. It is important that boundary spanners identify patterns and dimensions of stakeholder group identities early on especially when varying scales of governance are at play (Cheng and Daniels, 2005). Recognizing that watersheds often occur at multiple geographic and jurisdictional scales, boundary spanners need to be cognizant of participants’ unique needs and values. In this way, they can develop a sense of community encouraging stakeholders to connect and identify with others’ concerns about the watershed and community as a whole (Cheng and Daniels, 2005).

Findings by Cash et al. (2006) reinforce the idea that knowledge is perceived differently at various levels or scales, which is a result of individual perceptions as to what is credible, valuable, and legitimate information, and whether or not it is important. This “plurality challenge” (Cash et al., 2006, p. 6) can be addressed by a boundary spanner since this individual acts as an intermediary between the different levels or scales, perceptions, and interests, by assisting in the co-production of knowledge. This type of cross-sector, multi-stakeholder collaboration creates a more comprehensive watershed-based management approach (Enloe et al., 2017), allowing for a variety of discussion and debate.

Autonomy

Results of research on collaborative engagement consistently emphasize the importance and significance of stakeholder perceptions toward other stakeholders, whether stakeholders be from public agencies, nonprofit organizations, or the local community. The notion that stakeholders perceive boundary spanners as somewhat independent or autonomous from their home organization is also significant and the key to successful collaboration. Schotter et al. (2017), whose study was primarily conducted on boundary spanning in global organizations, acknowledged that a boundary spanner’s actions and effectiveness are influenced by both the organizational structure of one’s home institution and that individual person’s capabilities. That being said, boundary spanners can be viewed as direct representatives of their organizations tied to its beliefs and values, lacking autonomy and an unbiased voice. In addition, managerial motivations and one’s business identity can adversely affect their actions and effectiveness. Because a boundary spanner’s role is to cross-organizational borders and make connections, she is more effective when given a certain amount of autonomy to engage constructively with other actors (Williams, 2002).

Conflict

Stakeholders who have experienced a history of conflict with another actor in the IWRM process are more likely to express low levels of trust presenting a challenge to boundary spanners. Tense and conflicted history between participants is likely to result in lack of commitment and participation as well as feelings of suspicion and distrust (Ansell and Gash, 2008). On the other hand, blind trust and unusually high interdependence among groups of stakeholders may discourage collaboration among a wider set of actors. Ansell and Gash (2008) suggest that factions of any kind within the participatory process are less likely to favor collaboration. In those instances, when stakeholders come to the table with predetermined feelings and perceptions, boundary spanners must

work to remediate those low levels of trust and social capital. In fact, when there is a prehistory of conflict among participants, the development of trust becomes the most important aspect of the collaborative process.

Cooperation

The absence of conflict does not always result in cooperation or cohesion within the IWRM process. Participants, for one reason or another, may refuse to acknowledge perspectives different from their own. This may be the result of stakeholders not being given enough time to develop strong relationships, the complexity of the resource issue, feelings of marginalization, or other factors. The boundary spanner's role in this situation is more challenging yet can be overcome with early and transparent communication, continued inclusiveness, and more face-to-face interactions between stakeholders (Megdal et al., 2017). In those situations, where interest conflicts are not a significant factor, boundary spanners can work on improving the efficiency of the IWRM process. For example, a 1-day participatory workshop in Koraro, Ethiopia offered stakeholders an opportunity to share their understanding and perspectives of a water management project that directly impacted them. Agency officials discovered after listening to stakeholder concerns that a one-size-fits-all approach was ineffective and costly, and failed to acknowledge local citizens' preferences (Megdal et al., 2017).

Although boundary spanners strive to promote learning and build competence during the participatory process, the system is not always effective resulting in divided stakeholder relations. Because knowledge sharing is critical to strong cross boundary cooperation, boundary spanners can focus their energies into the quality of the engagement process. Utilizing experts and serious gaming (or role-playing) improves social learning and provides participants the opportunity to explore.

Summarizing Boundary Spanning and Integrated Water Resource Management

The bundle of attributes and abilities that define a boundary spanner is unsettled; nevertheless, an effective combination of the following characteristics is necessary to overcome the barriers needed for long-term stakeholder engagement: demonstration of independent thinking, good listening and communication skills, competence in power management, neutrality, and high integrity (Williams, 2002; Pirson and Malhotra, 2011; Delaine et al., 2015; Coleman and Stern, 2018). In some organizations, upper management chooses boundary spanners because they are well connected within their home organization and are perceived as trustworthy (Schotter et al., 2017). On the other hand, others are individuals who become involved because they want to be an active change agent or cross boundaries and establish lasting relationships (Williams, 2002). Boundary spanners who are perceived by stakeholders as more independent are often considered more trustworthy and viewed as less likely to have a hidden agenda (Thompson et al., 2016).

The specific role of the boundary spanner is critical to a successful IWRM process. The primary objective of a boundary spanner is often to create an environment where diverse stakeholders feel confident to express their opinions, share knowledge, and accept vulnerability thus leading to better collaboration and trust between participants. Boundary spanners who can make the decision-making process more transparent and less contentious encourage more knowledge sharing and participation from stakeholders. Of particular interest to the IWRM process is how boundary spanners can assist with information sharing, which includes both scientific and local knowledge. Grygoruk and Rannow (2017) refer to this as "horizontal interactions" and support the idea of using boundary spanners to help bridge that gap between complex scientific data and stakeholder needs. Sharing scientific and technical information at a level of comprehension, which can be not only understood but also applied, helps facilitate wider stakeholder participation, dialogue, and the associated social learning process that may take place in small group settings. Such information is valuable and should be utilized to aid in decision-making, but as Muñoz-Erickson et al. (2010) point out, disputes over expert knowledge can become a central point of conflict. These debates over issues of fact or information can incapacitate a collaborative process. It is critical that boundary spanners minimize the "us v. them" mentality between groups of stakeholders so that the conflict does not become so deep-seated that participation ceases.

Without a doubt, a primary focus of a boundary spanner is building sustainable relationships. IWRM involves individuals from a variety of professional and organizational backgrounds; thus, these collaborative encounters require boundary spanners to not only recognize but also manage these differences (Williams, 2002). This can be achieved by a boundary spanner maintaining a high degree of contact with her internal organization as well as the external environment. Zhao and Anand (2013) point out that boundary spanners dealing with highly technical or scientific information must often grapple with its complexity, and then must process, filter, and feed that information to external stakeholders. The challenge lies in ensuring that the information is not so distorted or complicated that stakeholders feel excluded and unwilling to negotiate.

As a result of their study on boundary spanning in global organizations, Schotter et al. (2017) realized the advantages to utilizing individuals who can interpret and clearly communicate complex information to others in negotiations. The researchers concluded that boundary spanners' work be modeled after a rubber band allowing for flexibility in mediation. This flexibility permits stakeholders within IWRM to act independently but still change directions when applicable in order to demonstrate alignment with others. Participants benefit from this type of participatory process because they can stretch to accommodate different perspectives yet remain within the confines of their organization's plans and policies. As boundaries become more complex with the addition of more diversity and perspectives, the advantages to the rubber band principle increase.

Even when IWRM stakeholders' interests conflict significantly, research has shown that the presence of a boundary spanner within the participatory process has been positive (Williams, 2002; Klijn et al., 2010; van Meerkkerk and Edelenbos, 2014; Coleman and Stern, 2018). Establishing sustainable and working relationships in complex networks takes on a variety of forms yet the primary goal is the same: cross borders, establish effective connections, facilitate good information exchange, and seek out shared meanings between stakeholders. Although boundary spanners seek to establish personal and lasting relationships between diverse participants and organizations, the danger of creating too tight of a relationship must be recognized. Williams (2002) warns that those networks that are overly reliant on these personal relationships may suffer when the boundary spanner leaves the network.

Conclusion

Although the opportunity to build trust between stakeholders within the IWRM process is crucial to collaboration and policy development, a boundary spanner's role reaches beyond simply trust building and facilitating communication. Today's water managers and political leaders face multiple challenges: climate change, natural events such as flooding and drought, the increasing impacts and risks associated with industrial discharge, urban sprawl and an ever-increasing global population. Those involved with IWRM must consider and engage with multiple actors with diverse perspectives and perceptions in hope of achieving collaboration across various sectors, organizational or geographic boundaries, and political alliances. Reaching across boundaries requires individuals who have the temperament to resist political pressure and provide balanced and accurate information. Environmental policy is often not based solely on scientific evidence, but rather influenced highly by human dimensions. Boundary spanners have the opportunity to work with and educate scientists, policy makers, and citizens on how to engage more effectively in public discourse so that environmental policy decisions are based on accurate and timely data and more readily accepted. (Cvitanovic et al., 2017). A goal of boundary spanning is to reduce the risk that science not meet the needs of decision-makers; the ability to identify contradictory evidence and conflicting perspectives early on in a process may minimize damage to further collaboration. Water management decisions must be seen as legitimate and not a vehicle for pushing particular agendas; scientists and others who have the skills to effectively inform policy at the right moment are needed. Bednarek et al. (2018) identifies these opportunities as "policy windows", and the opportunity to capitalize at these moments increases the likelihood that water policy decisions will be evidence informed and accepted by stakeholders.

Abstract

Countless people are leading the charge toward sustainability thinking and action, and it's not enough. Given the increasing urgency of human-caused climate change and its inevitable destruction, an expanded view of leadership—as generative engagement for change—is more essential than ever before. This article outlines twelve keys for generative engagement which begin with each individual challenging assumptions and beliefs about where humans stand in the complex, interdependent processes of life-as-it's-happening among millions of species within our shared ecosphere. Anyone who cares is called to embrace the role of “leader” and practice engaging—generatively—with others and our shared dilemmas.

My grandson, Sam, was 11 years old when I published my first article outlining the need for an expanded view of leadership for sustainability (Ferdig, 2007). I described sustainability leadership as “an emerging consciousness among people who are choosing to live their lives and lead their organizations in ways that account for their impact on the earth, society, and the health of local and global economies.”

Sam is now 24, working as a civil engineer for a major construction company in Chicago, Illinois. I ask myself, what has changed in the 12 years since I wrote about an emerging consciousness among people who care? I was concerned in 2007 about Sam's future as well as millions of children around the world. I'm no less concerned today as he and other once-children join the “order of grownups” who are presumably doing something to reduce the existential threats to human life on this planet.

“Our leaders are behaving like children!” Greta Thunberg, a Swedish teenager, said to world leaders at the United Nations Climate Change Summit in December 2018 (Holter, 2018). Her words were notable for those of us in the United States who are concerned as we watched our president announce the US withdrawal from the Paris Climate Agreement while eroding environmental protection policies in the United States. It seems we have not yet begun to recognize our interdependence as members of the human species, much less our interdependence among millions of species within our shared ecosphere.

The Past 12 Years

Much has changed in the past 12 years, as things do in complex processes of life happening in and around us moment-to-moment. People grow old as children grow up and economies ebb and flow. National leadership shifts with new elections and changing politics. The drug epidemic reaches crises proportions while scientists continue to conduct knowledge-expanding research, making remarkable advances in the fields of genetics, medicine, technology and neurology to lengthen and enhance the quality human life.

Climate scientists are urgently telling us that human-accelerated climate change is worse than they first thought. CO₂ levels are well beyond acceptable limits for life as we know it on this earth, glaciers are melting and water levels are rising more rapidly than previously estimated. Fresh water supplies continue to dwindle even as desalination research becomes more promising. Destructive storms, flooding and uncontrollable fires are becoming more frequent and intense costing too many human lives and billions of dollars. While the causes of changing climate patterns are many, the burning of fossil fuels and animal agriculture are two of the biggest contributors, along with deforestation according to the United Nations Intergovernmental Panel on Climate Change (IPCC), (2018).

Scientists further estimate that we are now losing species at 1000–10,000 times the natural rate, severely compromising the biodiversity benefits required for healthy ecosystems (Chivian and Bernstein, 2008). Human-accelerated climate change, deforestation, habitat loss, unsustainable agriculture, pollution and pesticides are contributors to rapid extinction (Earth Day Network, 2018). Kolbert describes the sixth mass extinction that is unfolding before our eyes. “There have been five comparable crises in the history of life on Earth,” she writes, “but this one is different: It's being caused by us” (Kinzig, 2014).

Equally dramatic has been the growing trend toward nationalism around the world, an apparently increasing need to distinguish between “them” and “us”, the people or nations we trust and those we can't, don't or won't. People fleeing oppression and violence in search of refuge are increasingly met with resistance wherever they go. Though we haven't yet begun to experience the massive migration to occur as communities along coastlines lose landmass to seawaters (Wallace-Wells, 2019).

Ideological polarities, such as, progressivism vs. conservatism and socialism vs. capitalism appear to be solidifying in the minds of neighbors, acquaintances, and family members who once shared similar enough views they could have thoughtful conversations about differing perspectives. Religious intolerance, growing disparity between the wealthy and poor, institutionalized injustices toward women and people of color, are examples of the complex variables that contribute to the steady hum of dissonance that too often erupts in random displays of hatred and violence.

While much good has happened in the last 12 years; overall, it's hard to say things have gotten better. It's as if the complex, unprecedented challenges of our day have prompted responses within society that are pushing us farther away from understanding ourselves and each other as part of the interrelated and interdependent web of life on earth.

Sam, I welcome you to the ranks of grownups who not only care about people, the natural environment, and finding solutions to the dilemmas we have created for ourselves, but are also willing to explore what it means to be a sustainability leader.

What Does It Mean to Be a Leader for Sustainability?

We learned a long time ago that meaning is in people, not words (Korzybski, 1958). When working with others I've found that tying down concepts according to textbook meanings tends to hamper the thinking processes underneath what it takes to bring a term such as "sustainability" to life in each situation. Though we can ground our thinking about sustainability in the Brundtland and United Nations World Commission on Environment and Development (WCED) (1987)—essentially, living today without compromising the resources needed for others to live in the future.

Numerous writers have adapted the concept of sustainability to fit business (Elkington, 1998) and community planning (Steward and Kuska, 2011) as well as other applications and contexts. Collectively, they tend to feature concern for the natural environment in concert with interrelated concerns for people, profitability, economic and socio-cultural realities, technologies and public policies.

Though whatever the application, for me, sustainability thinking and action becomes meaningful when people begin to consciously shift how they see themselves in relation to one another and the complex processes of life that are occurring in and around them every day (Ferdig and Ludema, 2004).

A "leader," as we use the term at the Sustainability Leadership Institute (SLI), is anyone—regardless of background, social standing, expertise or positional power—who takes responsibility for understanding and generating workable solutions WITH others for the ordinary and overwhelming challenges we encounter day-to-day.

Leadership, in SLI's view, is about the capacity to engage generatively with others to resolve problems, make decisions, and participate in meaningful action. It requires a conscious shift in how we see ourselves in relation to others and how we consciously or unconsciously assume the role of leader in today's society. It means letting go of the idea of leader as the one who knows, who is a visionary, strategist, expert, or the one who provides direction for a pathway forward. It also means letting go of self-certainty and ego that smart, often passionate, people who may think of themselves as leaders, tend to carry along with themselves as they offer their solutions and presume to guide others toward their suggested solutions for success.

There are innumerable books, models and theories of leadership that have direct relevance for sustainability leaders ranging from transformational leadership (Burns, 1978), to transactional leadership (Bass and Avolio, 1994), democratic leadership (Lewin et al., 1939), self-organizing leadership (Knowles, 2002), distributed leadership (Vygotsky, 1978; Spillane et al., 2004), participative leadership (House et al., 2004), resilient leadership (Duggan, 2009; Everly Jr. et al., 2009), regenerative leadership (Hardman, 2011), and collaborative leadership (Chrislip and Larson, 1994). Though none I've studied so far focus specifically on the perspective and practice of generative engagement as highlighted in this chapter, and which, I assert, is a fundamental component of leadership for sustainability.

The human heart longs for the health, safety and well-being for ourselves, our families, colleagues, neighbors, and by extension, people in our communities around the world. We long for a healthy earth, healthy democracies, healthy places to live and work with colleagues, friends and our families that sustain us. This longing surely transcends national identity, political party, economic standing, ethnic origin, and differences in our education.

Sustainability leaders recognize and tap into human longings in themselves and others. They recognize the dissonant undercurrent that appears to be growing stronger, louder, and more menacing each day. They work at becoming informed and aware, inspiring themselves, friends, family and neighbors to participate in meaningful change.

No doubt our ranks are growing. More and more businesspeople, social entrepreneurs, community activists, natural and social scientists, foundation administrators, and everyday neighbors are waking up and talking about the threats we are facing. Universities are embracing interdisciplinary sustainability-related curricula and forming consortiums with other universities for sustainability-minded activity (Hardman, 2011). Even a few politicians are speaking up about the threats of climate change (Hirji, 2019).

However, if we're serious about leading sustainability thinking and action, we must learn what it means to engage generatively, beginning within ourselves and working outwardly to engage with others and our circumstances locally and globally. Below are some keys for getting started (Table 1).

Twelve Keys for Understanding and Practicing Generative Engagement as Leadership for Sustainability

Over a lifetime of observations, experiences and study, I've learned that challenges are best resolved among those who are most immediately impacted by them, and who chose to engage in authentic interaction—whether in workplaces, boardrooms, city council meetings or living rooms. Further, I've learned that the processes for finding workable solutions are significantly enhanced by relational qualities of freedom, inclusion, inquiry, spontaneity and a shared belief in what's possible (Ferdig and Ludema, 2004).

Action research (McNiff, 2017; Reason and Bradbury-Huang, 2001) —systematic learning while doing— coupled with grounded theory development (Strauss and Corbin, 1998) have particular application in social science research in which circumstances call for immediate action, and learning occurs in the processes of participating in the development and practice of alternative actions. My tenure at a Midwestern electric power utility, as well as consultancy in the utility industry, small businesses, government, and nonprofit organizations, not to mention my personal and family relationships, have provided innumerable opportunities for formal and informal action research and learning as well as on-the-ground theory development.

Below, I describe 12 keys for understanding and practicing what I refer to as “generative engagement” developed from my accumulated learnings. I present them as an invitation to consider and begin to experiment with generative practices. Please note the terms “communication” and “human interaction” are used interchangeably with the term “engagement”

1. Discerning the Generative Engagement Difference

Communication—engaging with others and the world around us—is at the center of everything we do. We learned at birth it was an effective means of exercising power and control to get what we want in the form of food and warmth. As we matured we refined our ability to engage strategically: we learned stuff in school, how to have fun, make friends, get dates and ultimately engage with others in our work and personal lives to help make things happen.

Ego and self-interest have a way of creeping into our strategic engagement. Persuading people of our ideas because we believe they will benefit the greater good can be an ego-driven trap. Deception, too, is an engagement strategy for achieving our goals; information can be distorted, withheld, or generalized rendering it misrepresentative or meaningless.

Generative engagement doesn't resort to deception, manipulation or planned strategic advantages to achieve preconceived outcomes. Reciprocal engagement requires an awareness of our interactive and interdependent processes for generating life as it is occurring in the present moment. At the core of generative engagement are humility, a spirit of inquiry and an ethical responsibility to self and other. It means consciously bringing into existence with others what is mutually valued: for example, understanding, trust, good ideas, goodwill, forgiveness, hope, and synergistic energy for finding sustainable solutions.

We choose to engage generatively because we know that our own well-being, and that of those we love, depend on the well-being of the interconnected, interdependent network of life of which we are an inseparable part.

2. Understanding Human Engagement through the Lens of Science

The sciences of physics, biology, chemistry, computer technology and others have given credence to an emerging view of our reality not unlike the view that philosophers and spiritual teachers have been telling us for centuries: everything is interconnected. Not only are matter and energy—living and nonliving—interconnected and interdependent, they are continually moving and changing in response to one another and their circumstances through self-organizing interactions (Kauffman, 1995).

Complexity is simply a term that describes life as it's happening. It reflects the continuous life-giving processes of interaction among entities—atoms, molecules, organs, humans, plants, animals, ecosystems, cities, states, planetary bodies—that create connection, movement and change through relational interdependence. Complexity processes reveal anomalies and paradoxes that appear naturally in ongoing interactions; turbulence can build on itself, sometimes creating major perturbations that result in radical shifts in the interactive patterns, structural form and physical identity (Prigogine, 1996; Lichtenstein, 2000).

Focusing on human processes of interaction from a complexity perspective has profound implications for how we choose to see the world and ourselves in it, and how we choose to think and behave with one another in everyday circumstances.

Everything we do involves interaction in some form whether planting petunias, making a cup of tea or cocreating societies, governments, cities, products, services, wealth, poverty, climate change, other problems and their solutions. We are, right now—every moment—cocreating the world in which we live through our interactions within ourselves, with each other and our environments.

The frequency of interconnectivity among people and ideas, and the speed with which volumes of information can be accessed as a result of the internet, reveal valuable information in new configurations that contribute to previously unimaginable solutions. Though information exposure can also make it difficult to discern that which is valid from that which is wrong-headed, incomplete, obsolete and intentionally deceptive.

The processes by which we humans engage with one another and circumstances in our individual worlds—all seven billion six hundred million and counting of us—impact our relationships with one another and our natural world wherever we are (Louv, 2012).

3. Dancing With the Rhythms of Change

Learning to understand, accept, and navigate the complexity around us flies in the face of everything we think we know. It asks us to detach ourselves from desired outcomes, to let go of certainty, control and predictability in favor of emerging possibilities. It invites us to rethink the experience of changing.

Moore (2002) drafted a sketch to conceptualize the rhythms of change from a complexity perspective (Table 2).

Table 2 The rhythms of change.

Potential represents infinite possibilities, mostly unimagined; it is complex, unbounded, unquantifiable, unqualifiable.

Flowing is the first rhythm of change as we think conceptually. When energy and information are flowing and we are moving with the flow, our own energy is in sync with what is unfolding. We move along without disruption. Things are as we expect them to be.

Flowing is interrupted by the sensation of *Staccato*, a feeling of being abruptly disconnected. Some complexity writers might call this a perturbation, a subtle indication that something is changing. We may feel startled, surprised, jarred or blocked in some way.

When information continues to be so disconfirming that we literally feel things are breaking apart, we are in the abyss of *Chaos*. Our mental models for making sense of things no longer hold up. We try to control, hang on, leave, dispel our anxiety by doing something ... anything. Nothing seems to work.

When we are learning, we lean into our anxiety. We see that our resistance can teach us about what is important to us and why it is worth saving, or not. In *Lyric*, which is light and graceful, we slow down so we can attend to what has emerged. Our energy is paced, we are able to rest and think more clearly.

When we move into *Stillness*, we see ourselves differently. Our choices of reference—how we refer to ourselves in the new scheme of things—develop and expand. We begin to identify with a larger whole—something outside of ourselves that has value for us. We have a greater sense of relatedness and connection which quiets and replenishes us.

(Moore, 2002)

While Moore's drawing implies a linear progression through change, we know from experience that changing is anything but linear and orderly. Most of us have likely experienced a crisis in some form and found that we did, indeed, know how to recover and adapt to the new situation.

4. Appreciating Human Systems as Verbs

We tend to think of human systems as nouns, a reasonably stable entity with a boundary and identity to which we attribute objective, solid, human-like characteristics. Doing so lets us get away with assuming, when a problem arises, that it's a "systems problem." This way of thinking, speaking and behaving tends to reinforce a belief that "the problem is out of my hands," and, instead, is lurking somewhere in a dark corner of a system (Stacey, 2000a,b). As a result, nothing much changes, if at all.

Similarly, we tend to anthropomorphize a system's workings as if it's a human being. An organization is said to have a vision, mission and human-like values. Systems are often accused of not communicating with one another. The US Supreme Court even passed a ruling that says corporations possess personhood distinct from the individual human beings that comprise them, that is, their owners or stockholders, members of their boards of directors, managers and employees.

Complexity-process thinking reminds us that corporations, institutions, organizations, and other so-called systems comprised of human beings are, in fact, not nouns. They are processes of movement and change among people who are in continuous interaction with one another and their circumstances in relatively close proximity (electronically or physically) within more or less permeable boundaries.

Social theorists (Stacey, 2000a,b; Mead, 1934; Elias, 1989) suggest that an organization, or a collective of individuals, and the respective individuals participating in interactions related to the collective are two aspects of the same moving, changing, self-organizing and evolving processes, each forming and being formed by the other through continuous interaction in relationship as depicted by the Möbius strip below (Fig. 1).

Interdependence among elements of a moving, changing phenomenon suggests each is both enabled and constrained by the other in fluid self-organizing processes of interaction. The phenomenon of enabling constraints within the self-organizing processes of interaction represent a naturally-occurring means of control that inhibits the possibility of "spinning out of control" as more traditional thinkers might worry about.

5. Recognizing Contrasting Lifeviews and Embedded Cultural Paradigms

Each of us processes information through our unique lifeview filters. No two lifeviews are identical any more than our finger prints are identical. Our lifeviews are the result of our unique genetic makeup coupled with our accumulated experiences and influences since birth. Our lifeview filters tend to dictate how we see, interpret and understand what is going on around us, which in turn, inform our communicating actions. Included in our lifeviews are embedded cultural paradigms—worldviews—of which we are mostly unaware (Bois, 1978).

Most of us are familiar with Kuhn's (1997) idea of a "scientific paradigm" as an accepted theoretical framework in any particular discipline; and a "paradigm shift" as a revolutionary phase when discontinuities and anomalies in a particular discipline begin to erode long-held assumptions that prompt conceptual breakthroughs to new ways of understanding the natural world. The transition from Newtonian mechanics to quantum physics is an example.

One can trace elements of a still dominant cultural paradigm—worldview—in Western society today at least to the mid-17th century when empirical positivistic science methods, relying on reductionism, proofs of linear causality, measurement and objective determinations of truth or falsity prevailed.

Discoveries in positivistic science, in turn, fueled an industrial revolution that flourished about a hundred years later in the mid-to late 18th century. As manufacturing became the new driver of progress, scientific management (Taylor, 1911) and organizational structures (Weber, 1983) that featured hierarchy, control, standardization and measurement for organizing people and their work became commonplace in factories, workplaces, the military complex and ultimately educational and public governance institutions. Economic systems favored competition, profitability and accumulated wealth. Exploitation of natural and human resources contributed to the engine of a prospering society.

Generative engagement invites us to examine our ingrained lifeviews and cultural worldviews—assumptions and beliefs to which we've been enculturated and likely can't see them as anything other than "the way things are." Complexity-thinking in science is contributing to emerging conceptual views about how the world works and where humans stand in relation to the processes of life occurring in and around us. On one hand, we know about and espouse these new conceptual views as we go

Fig. 1 A Möbius strip while it appears to have two sides has a surface with only one side and only one boundary. It has the mathematical property of being unorientable. As such, it serves as a metaphor for the inseparable relationship between the individual and the collective, each forming and being formed by the other.

about our business. On the other, if we look closely at ourselves and others in the context of our everyday interactions, we can begin to notice the extent to which we're still mostly stuck in traditional ways of thinking and behaving.

Table 3 illustrates a distinction in embedded worldviews. By now I'm sure you've noticed the inherent flaw in the table as it appears. Presenting information as an either/or dichotomy is itself a reflection of a traditional point of view. While doing so may be a useful device for explaining variations of thinking, it entirely misrepresents the both/and features of our paradoxical reality.

Generative engagement may be best understood from an expanded postpositivistic, complexity point of view; however, there are times when more direct, controlled and predictive thinking and action may be called for. The value of starting from an expanded perspective is that the choice to operate from a traditionalist point of view in a particular set of circumstances involves conscious, self-monitored interaction intended to contribute to the overall generative dynamics for cocreating workable outcomes for a particular challenge.

6. Practicing Conscious Awareness

We all presume to be conscious when we're not in bed, asleep or anesthetized on an operating table. And certainly we're aware of what's going on around us just to make it through a day. So what's the big deal about conscious awareness?

From a generative engagement point of view, conscious awareness is an art to be developed and continually practiced. It mostly means intentionally paying attention to what's less visible in and around the things that grab our attention. It means being sensitive to human energies and values in the present—our own and others—rather than blindly forging ahead doing what we choose to do without considering the impact of our interactions with others (Scharmer, 2009).

Table 3 Traditional worldview of reality and expanding worldview of reality.

<i>Traditional worldview of our reality</i>	<i>Expanding worldview of our reality</i>
Characterized by proven claims of what is so grounded in positivistic, reductionist, empirical observation implying objectivity, certainty and predictability.	Characterized by provisional claims of what is so which acknowledges the <i>paradoxical nature</i> of continually moving, changing, self-organizing processes of life emerging and, therefore, presumes objectivity and subjectivity, certainty and uncertainty, predictability and unpredictability occurring at the same time.
People observe reality from a position outside of the phenomena they observe and, therefore, can make objective claims about the truth or falsity of characteristics of said reality.	People are an inseparable part of the reality they observe; therefore, their observations, interpretations and claims about the truth or falsity of characteristics of said reality are inherently and paradoxically both subjective and objective and cannot be otherwise.
Knowledge is an accumulation of proven truths in the form of aggregated empirical data derived from controlled experiments and studies.	Knowledge is an accumulation of provisional truths in the form of patterns, themes and successive approximations derived from documented participant-observations occurring in a particular situation.
Change occurs in primarily linear and logical pathways forward in time and space leading from cause(s) to effect(s) and, therefore, are presumed to be reasonably predictable. If <i>this</i> happens, then we can expect <i>that</i> result.	Change emerges in linear and nonlinear, logical and nonlogical, pathways in the context of complex, self-moving self-organizing interactions and, therefore, are presumed to be predictably unpredictable and unpredictably predictable.
People can effectively control, manage, and influence outcomes by way of the power (in its various forms) they hold in relation to others.	People have limited ability to control, manage, and influence emerging outcomes given the dynamic power relationships inherent in the complex interactive processes of life happening.
Power can be attained and held by individuals and groups through various means (e.g., knowledge, information, position, physical force, and psychological manipulation) often unequal in relation to others.	Power is relational process that continually moves and changes in the context of complex interactions among individuals and groups in relation to their moving and changing circumstances.
Disagreement and conflict are the result of two or more individuals, and/or the organizations with which they identify, drawing inaccurate conclusions about an objective reality.	The relational and unequal power dynamics create natural tension that both <i>enables</i> and <i>constrains</i> emerging self-organizing outcomes within limits of control.
A paradox is contradictory information creating confusion, misunderstanding and, therefore, is a problem to be solved.	Disagreement and conflict are natural processes among individuals, and/or the organizations with which they identify, as they seek understanding of one another's unique perspective of a moving and changing reality.
Human engagement represents strategic human interaction for accomplishing desired outcomes, i.e., achieving agreement, developing a relationship, managing a work group, or expanding knowledge and understanding needed to fulfill individual, organizational or community objectives.	Paradox is a common feature of complex interactive movement and change creating dissonance that contributes to emerging novelty and change.
	Human engagement represents complex processes of human interaction occurring between and among interrelated, interdependent people engaging in a self-organizing phenomena of life perpetuating itself

Conscious awareness is a meta activity, something for which humans have a distinct advantage over most other life forms (Bois, 1978). For example, we are able to think about our thinking—which is a form of engaging with ourselves. In so doing, we might choose to challenge our long-held assumptions about a belief that may no longer hold water.

Conscious awareness—intentionally noticing—provides information from which we can evaluate and adjust our real-time interactions with an intention of cocreating space for generating understanding and mutually advantageous outcomes with another. Below are areas on which to focus one's awareness.

Being Aware of Oneself—The better you know yourself and the more comfortable you are in your own skin, the easier it is to be your authentic self with others. In addition to observing yourself in action and making real-time adjustments to strengthen a generative dynamic, you might also journal your thoughts before or after the fact. That act of writing can increase your clarity.

Being Aware of Others—This is the time to practice empathy, no matter how far you are from relating to another individual. Acknowledge the whole person: physical, mental, emotional, spiritual. What are they experiencing? thinking? feeling? What might have influenced their lifeview? Listen genuinely. Open yourself to learning. Check out your understanding of what you are hearing and seeing with them.

Being Aware of Immediate Dynamics and the Larger Context—Pay attention to nonverbal communication, that is, tone, expressions, posture, attitudes of people involved. Notice the feeling in the air, the invisible energy in the room. Do your homework to scan the larger environment of things that might affect the immediate circumstances and interactions as well as multiple perspectives related to the challenge at hand.

7. Pausing, Reflecting or Meditating

Stop! Let your practices for enhancing your awareness catch up with you. Find a dark sky and look up at the stars. Or a closet. Breathe slowly and deeply while you're there.

There are no rules for pausing, reflecting or meditating. Though doing so often requires deliberate action in our crazy, busy, high-pressure realities. The benefits, according to testimony by many who have learned to make this a daily practice, are many.

An NYU study of 20 meditators (Buddhist monks and nuns) detected numerous neurological benefits from meditating: (1) cultivates attentional skills, (2) points to an ability of the brain to change and optimize itself, (3) reduces the psychological wall between meditator and his environment, and (4) facilitates naturally-occurring self-reflection (Danzico, 2011).

There are as many ways to pause and meditate as there are people who do so: guided meditation, meditation with music, with others, lying down, standing up, seated a certain way, walking, or enthroned on a mountaintop.

Try closing your eyes and breathing deeply: in 1-2-3-4; hold 1-2-3-4, out 1-2-3-4, hold 1-2-3-4 and repeat for 2 min, then 10 min, working up to longer. Empty your mind of thoughts; when a thought appears, gently push it away. Be patient with yourself. It gets easier with practice.

8. Being Ourselves with Others

To be oneself with others is yet another paradox. We instinctively try to fit in with the crowd, put on our professional selves with clients, or put on our attractive, clever selves when going out on a promising date. We also know the feeling of being our "shoes off" selves when we're at home with trusted friends and family members.

Maybe there are parts of your core self you don't like and want to keep to yourself. Or maybe you think you won't measure up to who you want people to think you are, or what they expect you to be. Who is the real self in these situations? Of course they're all real. And yet, there's a core of who you are that sits at the center of your soul. That's the part that people want to know—and the part you want them to know when you're communicating generatively.

Being ourselves with others is a practice in honesty—first with ourselves (Morgan, 1976). Remind yourself of core integrity questions: Who Am I? What do I stand for? What am I up to? What do I hope to accomplish here? now? before I die? Speak truthfully. Tell it straight. Aim for transparency. But mostly, cut yourself some slack. You are a worthy person as you are. Be that person with others.

9. Managing Ourselves

As practices one through eight above imply, the only person over whom we have any significant control is ourselves and our own thinking and behavior (Stacey, 2000a,b). Others may choose to emulate our orientation and behaviors and, thus, relax into the rhythms and energy of participation, collaboration and co-construction of a shared reality. Or they may not.

Multiple orders of self—A simple way to imagine your capacity to manage yourself in the present moment is to think of multiple orders of yourself occurring simultaneously, each self having slightly more insight and control over the self just below. Your ACTOR self is at the base tier of being, and just above is the OBSERVER self that may have just watched the ACTOR self say something snarky to the difficult person you are negotiating with. The THEORIZER self above OBSERVER self recognizes that the snarky comment is not at all helpful for encouraging the generative dynamic you're hoping to cocreate with this person for finding genuine solutions. The DIRECTOR self, just above the OBSERVER self realizes the ACTOR self needs to act fast, humble itself immediately, and try to say something encouraging to dampen the expressed negativity (Bois, 1978). Most of us probably do some version of managing ourselves as described, but may not consciously direct our attention to do so when we are consumed with our ACTOR self doing its own thing in the dynamic swirl.

Assume personal responsibility—Assuming responsibility for our own thinking and actions that contribute—or not—to generative engagement may seem like a no brainer. Though in the heat of interacting with, say, belligerent or ill-informed people, assuming responsibility for generating understanding (Stacey, 2000a,b) goes a long way toward building relationships and resolving mutual challenges.

Hold ourselves accountable—Veteran Organization Development professionals, Howard and Sue Lamb, once introduced a term—DWYSYWD—to a power plant maintenance crew with whom we were working. The acronym stood for *Do What You Say You Will Do*. The next day the crew plastered a big sign on the power plant wall: DWYSYWD! I've noticed people come up with all kinds of creative tricks for holding themselves and each other accountable, once they acknowledge to themselves their responsibility for doing so.

Seek feedback—Talk to other people, your collaborators, workmates, nemeses and so on. How do they experience you and does it match how you see yourself? Sure their views will be subjective. So is yours. Work with it. It's good information.

Listen to ourselves—Trust your inner voice to give you clues, or maybe a shake down, if you're out of sync with what needs to be happening. Are you pretending you can stand outside the circumstances of which you are a part—judging, analyzing, blaming, intervening, advising or attempting to fix a problem? Or are you participating with a genuine intention to generate understanding and possibilities with people in a situation you probably helped to create?

Move with relational power dynamics—Power, too, moves through interactive processes instead of being held as a possession by some, and not others. While some people are more enabled or constrained than others at any given point thus making the relative distribution of power unequal, in time, people and circumstances inevitably shift and evolve in the dynamic interrelationship (Elias, 1989; Stacey, 2000b). It makes sense to be aware of changing relational power dynamics and move with them.

10. Embracing Conflict Fearlessly, Openly and Respectfully

Conflict is a natural phenomenon of our interactive processes and a fruitful source of learning and change that many of us haven't yet learned to appreciate and fully utilize. In fact, unless we're drawn to exacerbate conflict in what we see as a zero-sum game of COMPETITION seeking to win whatever the cost, we tend to turn ourselves inside out and upside down to ACCOMMODATE others, thereby failing to assert a potentially useful point of view, or to simply AVOID conflict altogether. We're sometimes able to get to a COMPROMISE through constructive interaction, each party giving up some to reach a workable agreement. Though, ideally, we COLLABORATE with the intention of jointly creating new ideas and better solutions than anyone could think up alone (Thomas, 1976).

In the cases of compromise and collaboration, we first have to acknowledge and respectfully confront our disagreements. Why not practice openly embracing conflict? Muster your courage and confront the sense of conflict you're experiencing with another respectfully, with empathy and compassion. Talk with them and listen carefully for understanding without trying to persuade them of anything. Think of the amplified emotional dissonance you and others may be experiencing underneath a conflict as a valuable source of creative energy that needs to be tapped.

11. Watching our Language

We construct our worlds with language and symbols. Yet, in so doing, we tend to forget that our language and symbols are *not* the things they represent, but merely tools we have to work with to generate shared meaning. Further, whatever the words or symbols we use, we can assume our intended meanings are filtered through another's unique lifeview sensory screen and will never be understood exactly as we intend, nor will we understand another's expression exactly as they intend (Bois, 1978).

This is so even when we communicate as carefully and truthfully as we can. Never mind the way we use language and symbols to intentionally or subconsciously misrepresent reality as we know it to be.

Nonetheless, there are practices we can use to help us make our language as accurate as possible as we seek to engage generatively with others (Korzybski, 1958; Bois, 1978).

- Recognize what are referred to as 'over/under-defined' terms, and there are many. Take the words 'sustainability' or 'leadership' as examples. They are under-defined, given that they are abstract terms that are understood uniquely by each who hears and uses them. Yet, they are also over-defined to the extent that would-be experts and writers attempt to nail down with reasonable certainty what the terms mean, and speak of them as if the words-symbols are the things they represent. A sustainability leader practicing generative engagement participates in processes for co-constructing meanings of concepts and terms in the context of their interactions with others in each particular situation.
- Avoid "allness" words when making a claim. For example, avoid words such as "always," "all," "never," and "absolutely" and so on. Be skeptical of others' claims that include all-inclusive words. Omitting such words helps to qualify the pretense of certainty. Rarely is anything always the case.
- Avoid making statements that imply what may have been reasonably true yesterday or a year ago is also true today. For example, "They were resistant to the idea a year ago, though that's not necessarily the case today."
- Avoid making generalized claims about a group of things on the basis of one or a few occurrences within the group that may appear to be the same but are not. Fearing black men wearing hoodies, suspecting police officers of corruption, or distrusting politicians are thought traps in which it's easy to get caught when we read news stories of specific incidents.
- Adding simple qualifiers to your claims can do the trick. State what's true for you without assuming it's true for anyone else. For example, "I have it be that you're entirely overreacting!" Other examples of qualifiers: "In my opinion, ...," "The last time I saw him ...," "From my point of view, ...," "This may be the case, depending on ...," "In this particular situation, ...," "For me,..."

12. Learning as a Way of Life

One can't engage generatively without presuming there is more to learn in any situation. We each naturally filter whatever gets through our mental membrane just to make sense of the infinite stimuli bombarding us every moment. Therefore, we can assume information is left out, maybe really important information (Korzybski, 1958; Bois, 1978). Further, because of our

complex, ever-moving and changing reality, nothing—including what we think we know for certain—stays the same from one moment, year, decade to the next (Stacey, 2000a,b). Information begets information, learning begets learning, new insights and discoveries are generated every day just as misinformation and false truths are generated, and sometimes actively disseminated, daily.

Thinking critically—evaluating the veracity of information we take in—is a very real part of learning as a way of life. Critical thinkers are skeptics—the opposite of a ‘true believer’ described by Hoffer (2010). Critical thinkers question, demand multiple points of view and validation for claims they and others make. Critical thinkers know there is seldom a single right answer to resolve a complex a challenge. Instead, they engage with others to expand their understanding and points of view in the processes of generating possibilities.

Two professors at the University of Washington, USA, designed and cotaught a course entitled, “Calling Bullshit: Data Reasoning in a Digital World.” Their goal is to attract students of every discipline and expose “one specific facet of bullshit” a week, thus enabling students to discern the veracity of information they hear in the news (McWilliam, 2019). This is a great example of learning as a way of life!

Action research and learning, the notion of formally and informally observing and learning while doing, as well as reflecting on what was learned after a situation, has already been mentioned as a key to understanding and practicing sustainability leadership as generative engagement.

Conclusion

My hope is that as you’ve been reading, you’ve been giving consideration to the idea of leadership for sustainability as generative engagement for understanding and responding to the dilemmas before us. Perhaps you’ll experiment with some of the practices. Maybe you’ll share an idea or two with others who care about humanity, the natural environment, and what it is we can do to begin to shift the trends of destruction, exploitation and inequity in our local and global communities. Our ability to engage generatively with ourselves, one another and our environments may be the sole means for evolving ourselves collectively toward a life-giving consciousness and future.

Abstract

Despite the overwhelming need for humanity to collectively cooperate in engaging in pro-environmental behaviors, there remains a constant and consistent trend of human behaviors which negatively impact environmental systems. Understanding the factors which contribute to environmental behavior and the ways in which this knowledge can be utilized to generate pro-environmental behavioral shifts is critical for the future of a sustainable human existence. In this article, I will evaluate the impacts of leadership on human behavior through communication, conflict, and education. Skillful application of these principles can produce positive results in shifting human environmental behaviors.

As human beings all sharing the same planet, one might assume that preserving the natural systems and processes which sustain our existence would be a commonly shared priority. However, the truth is far more complicated and much less straightforward than one would initially hope for. As a society we have made great strides in advancing our knowledge of how the world around us functions, yet in doing so we have forgotten to pause momentarily to reflect on how our individual behaviors impact these natural systems and how the complexity of the human condition dictates our behaviors. This article examines relevant literature in an effort to explore the roots of environmental behavior and the influence exerted on it through leadership activities such as, communication methodologies, conflict, and education efforts. In doing so, the goal is to broaden the understanding of the factors which serve to dictate human environmental behaviors, providing insight into areas where change can be most readily gained as well as concepts which would benefit from continued research efforts.

Current Situation

Human society, much like any other natural system, is in a state of constant flux. While human society rides a wave of ever-advancing technology and societal interconnectedness, the decades-old problems of understanding and controlling human impact on the world at large has changed and grown as well. Due to science and technology advancement we are able to examine the world around us with ever-increasing precision; uncomfortably so in many ways. This power has provided humanity with the tools to identify and pinpoint the true extent of the torque exerted on this planet's natural resource systems by ever-accelerating natural resource consumption and natural system modification. While this information has become easier to access than ever before, the will and desire from the public to make the changes necessary to halt negative and destabilizing mankind-mediated events has not increased at the same rate as the damage has escalated. Currently, political affiliation, not scientific data, often dictates the beliefs and behaviors of many individuals regarding sustainability and environmental behavior; while debates are waged about the existence of climate change—a step backward if ever there was one.

While environmental behavior is the core of this literature review; behavior itself cannot be examined in a vacuum. More than ever, environmental behavior is increasingly being shaped by external factors in society today. Leadership through communication, conflict, and education can be key in molding the societally accepted behaviors humanity currently demonstrates.

Literature Review

Environmental Behavior

Amel et al. (2017) postulated that human behavior is centrally responsible for the critical conditions of the ecological systems we rely on to sustain human life, and that instilling guilt or fear in people is doing little to shift these behaviors. Worryingly, educating the citizenry—a favorite tactic for decades—still results in the same stagnant and environmentally destructive behaviors occurring

(Amel et al., 2017). Kollmuss and Agyeman (2002) illustrated that the models most often used to address these behaviors center around linear models from the 1970s which have since been proven incorrect. These linear models dictate that environmental knowledge will lead to changes in environmental attitudes; ideally leading to the desired pro-environmental behaviors (Kollmuss and Agyeman, 2002). This simplistic model of understanding behavioral drivers has blossomed and grown into an accepted practice to achieve environmental behavior modification, despite application of these methods resulting in repeated failures. Application of this model can even be observed today in educational initiatives targeting the public in the hope of educating for eventual behavioral change; sadly, these programs too fail to demonstrate consistent measurable outcomes.

From the outside, these behaviors resulting in environmental harm would seem counter intuitive, and the resulting damage to necessary systems would seem obvious. However, that is not the case. Amel et al. (2017) attributes this lack of awareness to the fact that industrialized people are so far removed from natural processes and systems that there exists a disconnect between nature and humankind. It is reasonable to assume that humankind is capable of reacting to direct experiences in immediate proximity, but the capacity to react to indirect experiences is very limited in comparison. Kollmuss and Agyeman (2002) described that immediate and tangible perception of many environmental crises simply does not exist. Kollmuss and Agyeman (2002) furthered this by pointing out examples such as radiation and atmospheric greenhouse gas accumulation as being representative of non-immediate and intangible results of ecological problems, which are often slow to develop and gradual in their increasing intensity—traits which make them harder to perceive for humans who excel at identifying drastic alterations in their immediate environment.

All this serves to further the idea of a behavioral disconnect between humanity's actions and the corresponding reaction in natural systems; reactions which humans are poorly designed to perceive. To understand the roots of human behavior we must understand that social norms act as the underlying driver of all behaviors, pro-environmental or not (Amel et al., 2017). The thought of rejection or indifference from the social group one ascribes to is a far more powerful motivator than an informational pamphlet; rejection is a direct experience with tangible outcomes unlike many environment issues. Due to this factor, continuing psychological research is delineating the ways in which these social norms and constructs can be modified in the future to produce sustainable behavioral actions (Amel et al., 2017). To not pursue the direct connections between psychological sciences and environmental behaviors is ignoring an invaluable explanatory tool for evaluating the mechanisms which dictate our human-nature interactions.

Leadership and Environmental Behavior

Leadership is one of the most powerful factors which shapes human behavior and is recognized as critical for producing a change in behavior as well (Evans et al., 2015). Manolis et al. (2009, p. 881) defined leadership as, "inspiring and mobilizing others to achieve purposeful change." This definition is well suited for the realm of environmental behavior, as the leadership which is sought to create new sustainable and environmentally conscious behaviors will have to act as an adaptive agent for inspiration and mobilization.

Leaders must work to create new values among others; values which provide the motive force to change behaviors (Manolis et al., 2009). Action and reflection cycling will be a key factor of leadership, with the ability to adapt and overcome the change-resistant individuals or social groups whose hesitation lies rooted in fear of unfamiliarity and disruption; albeit without generating direct opposition to the proposed changes (Manolis et al., 2009). This value-changing and value-creation task will be of the utmost value over time, as the values which are prized by groups and individuals alike are more likely to influence attitudes and resulting behaviors (Manolis et al., 2009).

In referencing leadership and behavior, it is important to understand who or what may assume a leadership role. Leadership is often classically associated with a key individual or position, which then performs as a traditional fixed-point of power within an organization or societal group. However, recent research by Evans et al. (2017) suggests that key individuals in a position of authority are not the sole source of leadership and should not be viewed as essential for leadership to take place. Rather, a diverse group of agents can provide a broad and detailed leadership service through the positive and negative influencing of group goals (Evans et al., 2017). With the previously stated definition of leadership referencing the ability to inspire and mobilize, it is important to point out that there is no required position of power or singular skillset that must be possessed to carry out this task—all engaged actants can provide this, it is not only reserved for a charismatic individual occupying a key position of authority (Evans et al., 2017). However, a pluralistic leadership view, one which does not assume that leadership is a singular and unequivocal good, is needed to understand that the sole presence of leadership itself does not automatically equate to positive environmental outcomes (Case et al., 2015). An undercurrent in our nation today being fueled by charismatic leaders opposing pro-environmental behaviors is guided by strong leadership. Regardless of the source of the leadership, the goals and motivations of the leader must be considered when assuming intent when seeking behavioral changes.

Leaders and Communication for Environmental Behavior

Often the communication style and method utilized by leaders is not considered when referencing behavior, but the role they play cannot be understated. In particular, leaders must consider the framing of messages, the succinctness of the statement, and the phrasing of the dispatch which can be formulated to increase the palatability of the concepts being communicated—ideally generating acceptance and value/behavior modification.

Lakoff (2010) pointed out that in today's society there is an overarching political connotation that enters into environmental discussion due to the moral-value tags assigned (or unassigned) to environmental issues which are now closely associated with conservative and/or liberal parties in the United States. While Lakoff (2010) commented that it would be ideal if these political valuations were not associated with environmental issues, this is however the current reality and it is vital that steps are taken to understand how careful framing and communication strategies reinforce these political positions. The conservative party in particular was lauded for the consistent messaging which effectively communicated the central values and views held by the party and its constituents; providing a simple, calculated, and compelling communication methodology to reinforce party values (Lakoff, 2010). Lakoff (2010) cautioned that a thorough understanding of the framing perception system of the human psyche along with careful composition of the messaging that is to be conveyed is critical to avoid potential communication pitfalls. Talking in terms of values while framing issues in a moral valuation context which provides story references that engage emotions and highlight personal values provides a recommended approach to communication with the general public (Lakoff, 2010). Lakoff (2010) also stressed the importance of avoiding jargon and focusing on real/local concerns when attempting to forge bridges of communication and influence behavior.

The phenomenon of motivated reasoning or cultural cognition, a concept which describes the situation which occurs when an individual favors the perception and cognition of information which serves to reinforce their currently held viewpoints and worldviews (Myers et al., 2015), is essential for leaders to understand when crafting messages. This confirmation bias can often result in individuals rebuffing messages targeted at them which run contrary to their personal beliefs or the belief structure of their chosen political or social affiliation group. Myers et al. (2015) went on to posit that simplistic or preferably numeric messages from trusted sources which are perceived to be independent can promote greater receptiveness to information dissemination and may lead to the individual self-identifying their knowledge gap and thusly seeking to fill it independently. However, this is followed later with the assertion that this messaging may backfire with those who automatically have a disbelief in the root of the environmental messaging, i.e., climate change (Myers et al., 2015). This illustrates a problem with messaging and simplicity, the individual may not be receptive or trusting of the source if they are already predisposed against the concept due to a closely held personal belief or value.

Whitmarsh and Corner (2017) further dove into the uniqueness of those having right-leaning views, focusing on the beliefs and communication methodologies that are closely tied with these political views. Perhaps most interestingly, in today's society public climate change engagement is most heavily influenced by the political associations and ideologies a person ascribes to (Whitmarsh and Corner, 2017). While surprising, the partisan nature of many facets of society is more pervasive today than at any time in history. Whitmarsh and Corner (2017) detailed the results of an engagement study targeting right-leaning groups with carefully framed and crafted pro-environmental messages which would typically be met with resistance. After evaluating the response to these targeted messages, the authors deduced that individuals responded better to these framed messages.

Behaviors cannot be changed without communication from dedicated leaders. Therefore, the value of carefully designed and framed messages capable of reaching the target audience cannot be understated. The initiation of constructive dialog with guarded and previously-distanced audiences, coupled with the elimination of senseless and repetitive pandering to those already in agreement, will provide a path toward pro-environmental behavior generation (Whitmarsh and Corner, 2017). The communication methodologies and techniques leaders employ to illicit these behavior shifts are critical, invaluable, and merit further study and research.

Conflict and Environmental Behavior

While conflict may not be considered one of the first primary factors thought of when considering actions which shape behavior, conflict is inevitable during efforts to shift values or behaviors (Manolis et al., 2009). Leaders play a pivotal role in conflict management, working to keep conflict at a level which is necessary for change, but below a threshold which produces direct opposition and resistance (Manolis et al., 2009). This conflict is necessary for change and is a fundamental part of the human condition which occurs when parties assert their interests at the expense of others (Redpath et al., 2013). The complexity of conflict also works to influence human behavior by dictating the ways in which individuals interact with each other, their trust for one another, the weight this trust carries, the depth of the levels of conflict that may exist between parties, the management techniques in conflict mediation this requires, and the realization that there are limitations to what can be done to mitigate conflict; all of these conflict-linked factors influence behaviors in differing ways.

Redpath et al. (2013) described the difficulties in the generation of collaborative efforts due to the deeply-rooted distrust which may be harbored by stakeholders engaged in a conflict. While high quality information, impartial intermediaries, and the need to push parties to identify problems as shared were discussed as integral to the conflict management process; the need for transparency on all parts was repeated time and time again as the most important factor in the process (Redpath et al., 2013). While conflict resolution is more likely if increased levels of trust can be fostered between the involved stakeholders, this trust building needs resources and a great deal of effort to foster the type of power-sharing and assumed vulnerability necessary to develop a long and lasting trust (Young et al., 2016). However, regardless of trust development and resource investment, no conflict will ever be fully resolved and eliminated, it will persist in some form or at some level in perpetuity (Redpath et al., 2013). A similar sentiment was also echoed by Gutierrez et al. (2016, p. 267) when they stated that "conflicts are often not resolved but rather managed," eluding to the amorphous nature of shared solutions and underscoring the limitations of conflict resolution.

Madden and McQuinn (2014) explored the complexities of conservation conflict transformation while expounding on the levels that exist within a conflict. While one may generally consider that the surface dispute is the real crux of the problem, often there is an underlying conflict or deep-rooted conflict below the surface that works to dictate the perceived outward behaviors (Madden and McQuinn, 2014). The evolution of a material or dispute conflict into a deep-rooted conflict over time can result in a simple problem turning into an intractable issue regardless of applied effort and resources. In this manner, conflict has an unparalleled control over behavior, possessing the ability to render any problem unsolvable. To this end, leaders must gain an expanded understanding of conflict and behavior interactions to better manage conflict.

Our natural resource and environmental systems do not naturally engage in conflict in the way humans do, this type of conflict only exists because of the interactions of people (Gutierrez et al., 2016). From a pro-environmental behavior point of view, these conflicts are vital to generate the required behavior changes needed to produce the sustainable outcomes desired. Natural resource and environmental conflicts will only increase in frequency as resource utilization expands and habitats shrink (Gutierrez et al., 2016), putting extra pressure on leaders and stakeholders to seek shared outcomes to manage these conflicts for the long term. While the desired outcome of any environmental conflict is a positive and pro-environmental behavior change, it must be understood that conflict will nearly always generate behavior change but if not handled appropriately it will not benefit the environment. This negative outcome can result in greater distrust and more difficult conflict management in future efforts, serving to further complicate the problem and create a greater hurdle to positive behavior outcomes. As these conflicts dictate current and future behaviors, the nature of new conflicts will change according to those new behaviors—creating a self-sustaining feedback loop which can be either positive or negative depending on leadership and conflict management efforts.

Leadership and the Use of Education for Environmental Behavior

As a leadership initiative, the influence of education on environmental behavior has been a long-term focus of study. Initial linear modeling suggested that the surest method to illicit environmental behavior changes was by educating an individual about natural systems with the belief that they would change attitudes and behavior after coming to the same conclusions as the scientists who collected the initial data (Kollmuss et al., 2002). While this linear: data—attitude—behavior model was later proven to be incorrect, this concept is still applied in many educational and outreach programs with subtle differences that can help to make the behavioral change outcomes a reality. Early childhood education models, undergraduate and graduate-level education programs, and large-scale educational overhaul propositions are all on the table regarding the capacity for education to influence behavior toward a sustainable and equitable outcome. As such, leaders seeking to generate pro-environmental behaviors have focused a great deal of energy and resources on the current and future education system and the power it wields to direct future behavior through capacity building.

Educating in the environment, about the environment, and for the environment are now the looking glass with which environmental education is observed (Davis, 2009). By initiating programs to educate in the environment the goal is to remove the distance between humans and nature at an early age, fostering relationships between children and nature which illustrate that humans are part of nature—not separate (Davis, 2009). Davis (2009) also discussed the ways in which education about the environment is conducted, which is the primary way in which most adult citizens of the United States received environmental education. In this manner teaching centers around the mechanisms and functions of the environment, but no effort is placed on demonstrating the inherent interconnectedness humankind has with the natural world. Education for the environment is the latest direction in environmental education, with the research-guided goal of building capacities in children to respond to future sustainability issues (Davis, 2009). While the engagement level from educators in early childhood environmental education ‘for’ efforts has begun to increase, little research is currently being conducted to understand the dividends and benefits which can be found from early childhood environmental education. This lack of research efforts is a phenomenon Davis (2009, p. 227) described as a “research hole” that is in dire need of being filled. These targeted early childhood efforts will do much to serve as agents for change in overcoming the behavioral driving factors often observed in the general public; while simultaneously addressing the low-level of current environmental education and building an environmentally-literate future population (Carleton-Hug and Hug, 2010).

Similar to the failings observed in the early childhood education system, collegiate-level education systems often fail to build the education “in” and “for,” eschewing it for education “about” instead. Thought, cognitive processes, and most importantly behavior will have to adapt and change if a shift in the methods of human interaction with natural systems is desired or required for future sustainable human—nature interactions (Walsh et al., 2015). From an educational standpoint this will require a fundamental shift in the way we define environmental education and what acceptable outcomes are defined as in the future. While dedicated to an evaluation of a graduate-level sustainability course, Walsh et al. (2015) demonstrated not just the changes in educational methodology required but also described the fundamental thought and behavioral shift associated with learning to work in a multi-disciplinary framework that is the core tenant of educating “for” the environment in a capacity-building education system for sustainability. This skill-building focus which is counter to the standard ‘about’ the environment protocol that is traditionally followed, allowed the students in the graduate program to learn “sustainability in practice” (Walsh et al., 2015:9) which provides for personal behavioral shifts toward positive environmental outcomes—a core focus of this education concept. While the focus on graduate-level students isolates the greater portion of the population from this vital educational experience, the program tenants of

behavioral-shaping capacity-building can be incorporated into other educational systems of varying levels—primary school through high school. By doing so, this allows for an expansion and integration of these ideals at all levels of education.

O'Brien et al. (2013) took the concept of environmental education reform to new heights, proposing that the behaviors needed to address current environmental challenges will require not just differing methodologies for environmental instruction techniques, but rather necessitate a shift in the ways in which problems are defined and solutions are proposed. O'Brien et al. (2013) proposed that viewing current environmental issues as technical problems with currently-known solutions is a disservice to the complexity of the issues and discourages the development of new educational methodologies and capacities. Both of which are necessary to generate the populational behavior shift needed for future sustainability. This focus on moving environmental education systems toward seeing things differently and viewing problems through an altered mental framework will generate friction within the current educational system. Resulting in an exposing of resistance and a lack of desire for change; exactly the sort of values the proposed experiential educational system aims to overcome through educational evolution (O'Brien et al., 2013). As a call to action for educational reform, O'Brien et al. (2013) provides a compelling argument which pokes holes in the current environmental education system and exposes the magnitude of the failures inherent to the current methodology. While not a specific blueprint that details the design and layout of the new systems which must be developed to build these capacities, O'Brien et al. (2013) does list a great many of the specific traits the new system must possess to create the behavior changes so badly needed.

Regardless of the focus of the educational reformation concepts, a common thread in recent environmental education literature is that “business as usual” is not working and environmentally-minded educational leaders are pushing for change. The currently observable behavioral outcomes of education dictate that the education itself needs to change if behaviors are to change. The undercurrents which are allowed to direct the flow of environmental thinking in society today are representative of the educational systems and the capacities they have built within the minds of the population they serve. This does not diminish the influences of other factors on behavior, however the ability to address environmental problems in a different manner and apply sustainability-driven skillsets developed during formative years applies a direct influence on behaviors later in life—environmental leaders know this. Focused development of these skillsets allows for future constructive environmental behavior and internal capacities that increase rationalizing and problem-solving abilities, skills that are vital for future sustainability. However, educational program shifts only address the portion of the population which is engaged in the educational system as a student, parent, or pupil; missing a great percentage of the population who will not benefit from these behavior-changing and capacity building opportunities. This illustrates that while education efforts can generate positive behavioral changes, it cannot be assumed that concentrating on this sector alone will produce the desired global changes needed for future sustainable behaviors; other influence factors will have to be employed to produce the desired positive behavior shifts. Educationally-focused leaders understand these limitations, but push for environmental educational reform as a key facet of influencing human environmental behavior long term through capacity building.

Conclusions and Future Study

Environmental behavior change is an intricate and currently incomplete puzzle that humankind desperately needs to continue to strive to solve. The complexity and staggering number of moving parts that make up behavior (environmental or otherwise) combine to form a confusing and hard to navigate maze littered with good intentions and poor or incomplete research. It would be easy to claim that we already have all the information and we must simply begin to apply it correctly to create positive behavior shift. Unfortunately, this sentiment is untrue and presumes that we fully understand the key drivers of human environmental behavior—when clearly, we do not. This is not to say that we don't have a grasp on several useful, key bits of information that can be applied to generate a positive change in environmental behavior—decision-making is possible despite the uncertainties inherent to this complex system. This is merely to point out that this is not settled science, more research and effort must be directed to exploring the psycho-social and political mechanisms behind environmental behaviors. Continuation of this research coupled with an acknowledgement that behavior is complicated and requires the evaluation and understanding of outside factors and influences will better allow us to determine how environmental behaviors are shaped and reinforced in human society. To this end, dedicated examination of behavior influencing leadership factors such as communication, conflict, and education must be continued to expand our knowledge of what roles each play in influencing individual and group environmental behaviors.

The role of leadership as a factor in behavior reinforcement and change is an area that merits continued research and investigation. It can be seen today that leadership functions can serve to reinforce both positive and negative environmental behaviors. As such, we would be remiss if continued focus on the role played by leadership and study of the composition and source of leadership itself was not performed regarding advancement in the understanding of environmental behavior. As a factor that influences many aspects of human activity, leadership is a powerful tool which will continue to be a focus of study for many years to come.

Leaders must consider communication methodologies and continually evaluate outcomes over time, as the psychological power they possess to change behavior and belief through concept framing and word selection become more valuable in the fight for behavioral change. While commonly shared communication methods call for brash and engaging language, studies have demonstrated that tactical application of communication techniques can serve to reinforce ideas and generate better overall acceptance of concepts and principles which may normally be dismissed immediately. Communication regarding environmental behaviors and supporting concepts without the benefit of these principles will not generate the kind of positive reception and behavior change that

is the ultimate goal. Continued dissemination of these communication concepts and further research into their application to environmental issues needs to be a key focus for researchers seeking to understand the factors to expanding pro-environmental behaviors.

While the focus on leadership and leadership roles expands, the skills that allow for the development and nurturing of conflict needs to be a point of emphasis for environmental behavioral change in the future as well. Studies indicating the value of conflict for the generation of change cannot be understated, highlighting the necessity for positive and progressive conflict development. When environmental leaders act an agent of change, conflict will always be present. The measure of the effectiveness of leadership will be in the ability to control the level of conflict and assure that it is generating progress toward a positive behavioral goal, rather than creating a disconnect and developing a rift which will drive apart critical actants needed to generate these behavioral shifts. This highlights the need for continued research into the complex and critical role of conflict, with a special focus on the behavioral dynamics which it directly impacts. Conflict, like other human sociological constructs, is a vital part of the behavioral puzzle that must continue to be assembled in an effort to broaden the understanding of the interactions between humans and the environment.

Much like the factors which seek to change environmental behaviors in the present, education for the environment and the methods of integrating this into the current educational landscape need to continue to be studied to change behaviors in the future—making education a key long-term focus for leaders. While the motivation for a large-scale overhaul of the entire educational system was advocated by reviewed literature, the possibilities of this type of deconstruction and reconstruction around a sustainability capacity-building system are unlikely to gain traction and acceptance by a public which still debates common core and the existence of climate change. Rather, an integrative solution which merges current practices with leading edge environmental education systems needs to be developed to address the capacity-building needs without gaining disfavor among the population whose children will be on the receiving end of this instruction model. The role which education plays in shaping environmental capacities for sustainability cannot be understated; making the continuation of this research and development of integrated teaching models that much more pressing as a leadership priority.

While many of the roles each individual factor plays in directing human behavior are known, the interconnectedness of each factor and the depth of contribution of leadership through communication, conflict management, and education on environmental behaviors is not yet complete. So, while it can be stated that leadership plays a critical role in determining human behavior, the extent of how effectively leaders utilize communication, conflict, and education is yet unknown. Continued research and study from the point of view of environmental behavioral impact is not just beneficial, but rather of the highest importance for the continued sustainable coexistence of humanity and natural systems. Once we understand how leaders can influence pro-environmental behavior, achieving positive environmental behavior change through the application of research outcomes will become a reality.

Abstract

Humans interact and are immersed in anthromes. They shape human experience and communities and in turn are shaped by human actions at a variety of scales. We become attached to places because they provide ecosystem services, connect us to community, and provide relative stability in a fast-paced world. Places bound nature-based livelihoods, recreational activities, and our learned aesthetics; shaping both our dependence and our identities. Humans in turn shape physical places to make them more in-line with our values and needs. These complex and shifting relationships form both anthromes and our sense of place. This article seeks to review how sense of place shapes and is shaped by anthromes and then explore how sense of place may influence, and be influenced by our responsiveness to climate change.

Humans interact and are immersed daily in anthromes. They shape human experience and communities and in turn are shaped by human actions at a variety of scales. We become attached to places because they provide ecosystem services, connect us to community, and provide relative stability in a fast-paced world. Places bound nature-based livelihoods, recreational activities, and our learned aesthetics; shaping both our dependence and our identities. Humans in turn shape physical places to make them more in-line with our values and needs. These complex and shifting relationships form both anthromes and our sense of place. This article seeks to review how sense of place shapes and is shaped by anthromes and then explore how sense of place may influence, and be influenced by our responsiveness to climate change.

What Is Sense of Place?

There is increasing awareness of the interlinkages between social and ecological systems, and the importance of understanding the dynamic and complex nature of their relationships to better manage for sustainability (Folke, 2006; Holling, 2001). How humans interact with places is of great interest to many disciplines ranging human geography to psychology and political science to philosophy (Antonsich, 2010; Gifford, 2014; Lewicka, 2011; Williams, 2014). In these various disciplines the sense of place lens varies, including identity (psychology), social process (sociology), culture (anthropology), rootedness (geography), engagement (political science) and stewardship (environmental science) (Ardoin, 2006). Connections also form at various scales from individual to nation states and in different types of places (built environments, natural environments, types of locations). Sense of place has developed as a heterogeneous field encompassing a diversity of concepts to address the relationship between people and place across these domains (Ardoin, 2006).

Most sense of place literature would agree that it is a socially constructed process (Stedman, 2003; Tuan, 1977), based on ongoing and dynamic interaction between people and their environment (Gieryn, 2000) that relies on the biophysical properties of the location (Jorgensen and Stedman, 2001). Common characteristics include the fact that sense of place is contextual, dynamic, interdisciplinary, conscious and/or unconscious and positive or negative. Sense of place is a layered concept, whose elements often include nature, culture and identity. The particular layers and importance of given layers varies by discipline and author. One model, suggested by Scannell and Gifford, includes the person and their experiences and emotions, the process of interaction, including cognition, and behavior, and the biophysical elements of the place itself (Scannell and Gifford, 2010). Concepts affiliated with the personal experience dimension of sense of place include place identity, place dependence, place attachment and place

meaning. These different but overlapping terms describe different components or lenses to consider sense of place, with identity focused on individual internalization of place, dependence focused on reliance on various ecosystem services, attachment based on emotions related to place and meanings related to the descriptors of place.

In this article, I define sense of place broadly as the dynamic collection of meanings, beliefs, symbols, values, and feelings that individuals and groups associate with a particular locality based on human experience, social relationships, and biophysical attributes (Chapin and Knapp, 2015). As we recognize the interdependences between social and ecological systems (described below), and the importance of feedbacks in shaping outcomes for health (human and ecological), sense of place can offer us a concept to consider our linkages to anthromes and how those linkages may change in a context of climate change.

What Are Social-Ecological Systems?

Social-ecological systems are dynamic, interlinked and interdependent systems that include both human and ecological drivers. This concept has gained traction as a framework for understanding the world, as well as generating theories about how the world works. It was popularized by interdisciplinary researchers exploring governance (Ostrom, 1990), as well as system dynamics (Berkes et al., 2002). Informed by ecological theory, Holling proposed a model for how social-ecological systems change over time (Holling, 2001). In this model, systems go through a series of linked stages dependent on levels of potential and connectedness. Within this model, there are a few places where systems can become trapped, including what has been called rigidity (high potential and connectedness) and poverty traps (low potential and connectedness). Rigidity traps are where a system is held in a development stage that is desired by people but increases the rigidity of the system, and therefore it's long-term vulnerability. Poverty traps are when a system gets trapped in a place of low potential and connections and doesn't have the resources to develop and transform.

Associated with social-ecological systems is the idea of panarchy, or how system components are linked across scales (Gunderson and Holling, 2002). Panarchy is a way to describe these linkages and acknowledge feedbacks between levels of organization. For instance, panarchy describes how social-ecological systems operating at different scales are linked by the concepts of revolt, where smaller scales invent, experiment and test potentially influencing larger scales, and remember, where larger scales stabilize and conserve via system memory or legacy (Gunderson and Holling, 2002). Both concepts (poverty/rigidity traps and panarchy) will be useful for considering the interaction between sense of place and anthromes. While beyond the scope of this article, several very helpful books and papers exist that lay out these concepts in more depth (Berkes et al., 2002; Folke, 2006; Gunderson and Holling, 2002). I provide this concise introduction as I think that it is useful to think of sense of place within a social-ecological systems framework.

What Role Does Sense of Place Play in the Development of Anthromes?

Anthromes are shaped and maintained by sense of place, among other drivers, which include economics, power and biophysical components. Sense of place functions at different scales, from the individual to group to region to nation. Over these spatial scales and over time the way we perceive and build meaning in places influences the management decisions we make, and therefore how anthromes develop.

For instance, most of the original wilderness areas in many parts of the United States are "rock and ice" wilderness because their economic value for other uses was low, while the utility they could provide in protecting water supplies was high. The biophysical realities of place led people to ascribe certain values to it, which then became inscribed in laws that extended that use over time. Current hikers, backpackers, climbers, and nature-lovers value the solitude, spirituality and remote recreation opportunities, but these locations are not the only possible places they could have experienced these values. History and meaning-making have made them what people experience today.

Anthromes are heterogeneous partially because of the heterogeneity of ecosystems and natural resources, but also because of sense of place and other factors described above. Heterogeneity in ecosystems can influence the anthromes that develop in place. For instance, in the cropland and rangeland anthromes of the Flint Hills of Kansas the rocky soil allowed the tallgrass prairie to remain intact where other areas were plowed for crops. Within this ecological heterogeneity, smaller ecological niches, the cultural heritage of settlers, and technology led to distinct patterns of sub-anthromes and development of different conceptions of sense of place (Isern, 1985).

As people become more mobile, their sense of place may shift from roots to routes (Chapin and Knapp, 2015). For instance, in the intermountain West there are many small mountain towns surrounded by primarily spruce-fir forests embedded in rangeland, seminatural, and wildland anthromes. These places have a long history of place-making, from summer camps for indigenous people to mining and or ranching communities, and now often as ski resort or summer off-road vehicle (ORV) playgrounds. The legacy of prior use has informed and influenced current development. For instance, mining communities often have a network of roads and trails that now support ORV travel and ski resorts are often surrounded by wilderness areas that protect scenic views. As tourism between places increases, the attraction of ski resort towns has grown, which may lead to the desire to maintain and increase certain types of places. Sparsely populated and naturally vegetated spruce-fir forests function differently than subdivided and managed ski areas in terms of hydrology, natural disturbance regimes such as fire and insects, and habitat. In addition to shifting anthromes, new conceptions of place may lead to the desire to steward or protect different types of places regardless of where they are located

(Chapin and Knapp, 2015). In both scenarios, sense of place influences human values, which in turn shape what a place becomes and therefore the anthromes that are present (Ellis, 2011).

Sense of place is dynamic and can shift based on personal and cultural values and biophysical realities. This in turn can shift the anthromes across a landscape. This is clear when we look at the anthromes that have increased in the last handful of decades and those which have decreased. Places that are valued tend to be reproduced more than those who have low value. For instance, the intermountain West has seen an increase in “ranchettes,” as people have wanted to own land and experience a more rural lifestyle yet in proximity to urban areas (Riebsame et al., 1996). We can also see this in the increase in “walkable” and in-fill developments within cities that attempt to recreate valued attributes of urban living (ability to walk, close commercial districts, interspersed green spaces) within dense settlements and populated woodlands.

What Role Do Anthromes Play in Development of Sense of Place?

Humans interact constantly with anthromes, but they are not always aware of the embedded human element within them. Internalized ideas of human-nature dualism, stemming from Descartes view of subject/object, leads many people to perceive nature as separate and distinct from human communities (Descartes, 1993). Without knowing it, their sense of place is influenced by historical human values and legacies, yet instead of reading them as constructed and interdependent on human behavior, they are perceived as “natural.” This may lead to naïve or unquestioned assumptions about place. For instance, while we now know that indigenous use of fire contributed to pre-European landscapes, they were originally “read” as completely natural systems, devoid of human influence (Stewart, 2002). This reading could lead to inaccurate suggestions about appropriate management for restoration.

Even when unacknowledged, anthromes connect communities of people who have lived in a place across time. This provides a type of system legacy and memory that can either maintain social-ecological systems in similar patterns over time or set them up for either a poverty or rigidity trap. System memory that helps to keep anthromes stable over time can be illustrated by irrigated hay pastures in the rangeland anthromes in the Intermountain West. Over time, these intense green places in semi-arid landscapes have become valued not just for agricultural production (their original intent), but also for wildlife habitat, open spaces, and view-sheds (Ellingson and Seidl, 2009). Agricultural land-trusts have leveraged this shift in value to place conservation easements on these resources which functions to maintain this land use, and social-ecological system, into the future.

A poverty trap can be seen in places that have had a legacy of extraction and where patterns of extraction continue. For example, historical mining communities may have pollution problems that lower the desirability of these places for habitation (at least for those aware of pollution impacts). Historical mining laws may also allow unsustainable ex-urbanization of high alpine locations, leading to the potential for future degradation (erosion, fragmentation, etc.). A rigidity trap can be seen in intensive monocultures in the mid-west that are supplemented with pesticides, fertilizers and ground water. While they produce much of the US food supply, they are protected from collapse by these influxes of resources.

Anthromes influence the ecosystem services produced and therefore the types of livelihoods that can be made in a place. This in turn restricts the types of place identity and place dependence that develops. In the mid-West cropland anthromes, legacies have led to monoculture agricultural fields that over time have homogenized surrounding landscapes and communities. As consolidation of land and specialization of crop has increased, small rural communities have often been transformed (Lobao and Meyer, 2001).

As people interact with different types of anthromes, they become aware of the very different suites of ecosystem services provided by each. This may allow preferences to occur—which can shift how anthromes are valued at different scales. These values are connected to individuals who have different levels of power and resources for impacting landscapes. For instance, scenic and recreational places may be more valued by wealthy “outsiders” for second homes, making it more difficult for traditional livelihoods (ranching or fishing communities) to co-exist based on rising land values and changing culture (Riebsame et al., 1996). It is also possible that over time and with increased mobility, those with power and resources can move to the anthromes that best fit their value set, effectively segmenting people by anthromes. It may also mean that the demographics of anthromes begin to stratify by economic class with those who can afford them able to live in “desirable” anthromes (agrarian landscapes, wooded suburbs) and those unable to afford it relegated to other types of anthromes. This can be seen clearly in home ownership patterns in desirable regions where second homes are more common in recreation centers, with local ownership relegated to less desirable communities (Hall and Müller, 2004).

How Does Climate Change Shift Sense of Place and Anthromes?

Climate change, as both a slow incremental and a fast threshold-inducing driver, will change both anthromes as well as our sense of place. As a slow driver of change, it will create trends in ecosystems and the ecosystem services that are available. This will shift both the livelihoods as well as the qualities and characteristics of places. In addition, climate change will create thresholds and rapid (and potentially unexpected) changes both to ecology, but also to social systems (markets, culture, etc.). These rapid changes will shift the way that human communities interact with ecosystems. It may remove key signifiers of what a place means to people or key relationships developed between people and place.

Human communities will struggle to understand how to live in places that no longer provide a key element of what defined and made meaning for the place. For instance, many agricultural communities in village and cropland anthromes have built social, economic, and ecological systems around the crop or product that they produce. The yearly tasks of cow-calf operators in rangelands of Colorado will be transformed if climate conditions require them to shift to a steer operation, let alone if they transition to growing crops. There will be a mismatch between cultural, social and work activities, a need to acquire new knowledge of production processes, and dislodge seasonal activities that support both the ecosystem, the economy, and the individual health and well-being of operators. A rancher who no longer irrigates in the spring may miss the flow of water, the smell of grass, or the comradery of haying. The same ripple of change will be felt for everything from grape and olive growers to corn and winter wheat producers.

On a larger organizational scale, the way climate change will impact sense of place is also evident in the National Park Service, a US federal agency driven by a place-based mission to preserve distinctive and functional elements of place. What does it mean when there are no glaciers in Glacier National Park or no saguaros in Saguaro National Park? The identity, and the “sense of place” ascribed to specific places will change. This loss of place identity, whether at an organizational or an individual scale, may either lead to feelings of loss, known as solastalgia, although other responses are possible (Albrecht et al., 2007).

Finally, climate change may shift, transform or endanger current anthromes. In this case, although the space still exists, the place will be gone. While place is dynamic and constantly changing, the temporal rate and spatial extent of these changes may be faster and at larger spatial scales than ever experienced before. This could potentially lead to whole social-ecological systems that no longer function, leading to rapid and jarring shifts to both dependence and identity. We are already seeing how climate-induced events are leading to mass displacement. In addition to the physical, emotional, social and psychological impacts to displaced persons, there may also be a shift in sense of place for people in locations receiving migrants, which in turn shifts local community structure.

How Does Sense of Place Influence Our Reaction to Climate Change?

In prior literature, sense of place has been described as a primarily powerful and positive influence in stewardship of places and well-being of people and communities. Only a handful of papers have pointed to the challenge of conflicting sense of place (Yung et al., 2003), NIMBY attitudes (Devine-Wright, 2009), or negative perceptions of place (Tester et al., 2011). There is uncertainty about how sense of place will influence human response to climate change (Devine-Wright, 2013; Masterson et al., 2017). It is possible that sense of place may lead to resistance, slow response, active adaptation or transformed sense of place.

Resisting Change

In response to climate change, residents with a strong sense of place may double down on efforts to keep the place the same. For instance, in one study agriculturalists with a high sense of place were associated with lower levels of transformability (Marshall et al., 2016). This could result in maladaptations that attempt to resist change, creating a rigidity trap. For instance, if climate change is changing climatic envelopes such that saguaros can no longer survive in SNP, one response might be to manipulate the environment so that saguaros can still exist. This may save individual plants but at large expense in keeping the system functioning as it did previously. This type of intervention doesn’t address the driver of climate change, but just one symptom of how it manifests itself. Since it focuses on a symptom (and not the underlying root), it may be maladaptive as it fails to resolve the problem. This response will likely be more common for communities or individuals with the resources to resist.

Slow Response

In addition to maladaptation, high levels of sense of place may slow response to climate change. In Western ranching communities, this might mean that those with longer residence time and dependence (older generation) choose not to take major actions to adapt to climate change or that this older generation retires or becomes unemployed early, leading the younger generation to tackle how their industry will adapt to climate change. It may also mean that the adaptive actions that are chosen are those that are compatible with existing identity and sense of place. This might act to conserve some of the elements of identity and sense of place that can be retained. It may also limit the range of alternatives that people are willing to consider. Since climate change will often manifest in slow or halting and gradual shifts which may reach a threshold or tipping point, it may be easy to ignore when slow or halting. This could result in unexpected transformations driven by tipping points rather than intended and planned transformations.

Active Adaptation

Alternatively, residents with a strong sense of place may be motivated to stay connected to the places that are important to them. This could mean a more active process of adapting and shifting sense of place and identity to climate change. Instead of ignoring or failing to perceive that ecosystems are co-constructed, people may become increasingly aware of how humans have shaped anthromes in the past, how they are doing so currently, and how they might do so in the future. This may lead to more honest and informed discussions of how human values shape ecosystem services, how power influences whose values are embedded in landscapes, and what the decisions of those in the present mean for generations to come. Individuals may begin to recognize the co-produced nature of anthromes and sense of place and actively work to shape both in a way that maintains their values and

important ecosystem services. This more active awareness of how people interact with place may facilitate the questioning of human-nature dualities and a more integrative sense of interconnections.

Transformed Sense of Place

The awareness of interconnection may increase system stewardship and shift conceptions of sense of place from local places that supply local ecosystem services, to a more regional, national or international sense of place where both sense of place and ecosystem services function at a wider scale. This might create different levels of “sense of place” as individuals begin to understand how they are a part of systems at different scales. Since climate change will likely “displace” some of the ecosystem services produced locally, people may gain a better awareness and appreciation for their dependence on services provided elsewhere. For instance, if wildfires in one area remove camping opportunities (at least temporarily) for local residents, they may develop a sense of place with other similar areas that have not experienced severe fires and where they can gain the same experience as in their prior locations. Described as “demos” by one author, this more globalized sense of place may allow better stewardship across scales (Williams, 2014).

Conclusion

Science and policy realms have typically prioritized quantitative and generalizable information in research and decision-making (Adger et al., 2011; Stedman, 2016; Tschakert et al., 2017). Quantitative data collection is relatively direct and the analysis is perceived as less subjective. This results in suggested actions that are often devoid of lived human experience (including attachment, emotion, and values) and are incremental (based on quantities of CO₂) rather than being transformative (Adger et al., 2011). There has also been a desire to produce generalizable or broadly relevant information instead of information related to case and place (Tschakert et al., 2017). Exploring locally-relevant and contextual information may lead to broader changes in behavior and beliefs. This requires more attention to the contextual factors that mediate how sense of place influences climate change response in places undergoing rapid change. It will also require structures to better “hear” and integrate on-the-ground perspectives into climate change adaptation. It also will be critical to think of other “connectors” in social-ecological systems that may play a similar role in response to climate change. These may include empathy, culture and spirituality, among others.

It has been suggested that sense of place could be a useful concept for better understanding social-ecological systems (Masterson et al., 2017; Stedman, 2016). In this article, we have seen how sense of place influences and is influenced by anthromes in a synergistic manner. We have also seen how climate change may influence anthromes and sense of place as well as how sense of place may influence our response to climate change. Current actions to address climate change are inadequate to avoid catastrophic results, including economic and ecological break down (IPCC, 2008). Sense of place, as a linkage between social and ecological realms, may be pivotal for adapting to climate change.

The role of sense of place in response to climate change is uncertain, but it will likely be substantial. If we consider the idea of panarchy, it may function to slow response and maintain systems in current configurations, or it may work to transform systems from the ground up from local to global scales. As a conservative force, it may increase system rigidity and resist change as actors in systems take individual and collective actions to keep the system in the same domain. As a transformative force, personal experience may lead to a paradigm shift in ideas about human-nature connection that influence local-scale adaptation but also how people relate to and interact with nonlocal nature. It is likely that sense of place is and will lead to a range of responses including those discussed within this article.

While urgent action is needed to address the reality of climate change, often touted individual (e.g., changing your lightbulbs), institutional (e.g., installing solar panels), national (e.g., carbon trading systems) and global actions (e.g., carbon reduction commitments) are necessary but not sufficient. Sense of place, by connecting to identity, attachment and dependence, may act internally to influence change at larger levels. While it has been acknowledged that transformation of social-ecological systems may be necessary in the context of climate change (Feola, 2015), current solutions fall short of transforming paradigms. As people wrestle with their connection to specific places, perhaps what they experience will create alchemic shifts that have the potential to transform our relationship with the natural world on multiple scales.

Abstract

The increasing need for people to adopt more environmentally responsible behavior in their everyday lives to secure the future of the planet has given zoos and aquariums both greater relevance and an additional challenge. It is no longer enough to help visitors understand ecosystems and animals and to encourage a love of nature; zoos and aquariums need to go beyond awareness and knowledge, and into the realm of behavior change. Facilities that house animals in human care are being called on to use these animals to engage, inspire and focus visitor attention on the urgent need for action to conserve animals and the physical environments that sustain them. Not surprisingly, therefore, modern zoos and aquariums are passionate about increasing their visitors' pro-conservation knowledge, attitudes and behavior (Ardoin et al., 2015; Ballantyne et al., 2019; Ballantyne and Packer, 2005; Moss et al., 2014; Pearson et al., 2014).

These aspirations regarding visitor conservation behavior require zoos and aquariums to rethink their educational programs and to explore new techniques for visitor interpretation (Gwynne, 2007; Mann et al., 2014a; Ramberg et al., 2002). Accordingly, zoos and aquariums now increasingly draw on social marketing techniques and an understanding of the psychology of conservation, as well as theories of learning and behavior change, to inform the design and presentation of their visitor interpretation and educational programs (MacDonald, 2015; Saunders and Myers, 2003). By complementing their repertoire of educational approaches with the use of behavior change theories and practices, zoos and aquariums are increasingly working towards supporting change in visitor engagement from "knowing" to "caring" to "acting" for animals and nature.

History of Zoo and Aquarium Education

The history of zoo and aquarium informal education has loosely followed the patterns of change over time in theoretical approaches to learning. A behaviorist perspective guided the early days, where the transmission of facts about the animals was paramount. This process occurred either via interpretive signage around the exhibits or through presentations from staff members (often called docents or guides). In both cases the information was presented to the visitor with little consideration for the individual needs of different visitors (Serrell, 1988). More recent approaches to zoo and aquarium education are guided by a constructivist approach to learning, whereby multiple opportunities are provided to visitors to enable them to create their own understanding of animals and ecosystems, building on their past experiences.

Increasingly, progressive zoos and aquariums are basing the design of their education and interpretation programs on behavior change theories such as Ajzen's (1991) Theory of Planned Behavior and Prochaska's (2008) Transtheoretical Model of Change (Wagner et al., 2009). These theories form the foundation of more recent approaches to influencing environmental behavior, such as community based social marketing theory (McKenzie-Mohr and Smith, 1999). The Connect-Understand-Act model proposed by Zoos Victoria is based on contemporary learning theories and uses current behavior change approaches (Lowry, 2009). The model has been used in the formulation of a number of the Zoo's campaigns and programs, and uses the unique advantage of zoos and aquariums—the opportunity to *connect* visitors emotionally to wildlife. Thereafter, the use of educational

resources can build an *understanding* of the threats facing that particular species and what *actions* visitors can take to alleviate the threat (Lowry, 2009).

Today, the relevance of zoo education is being increasingly scrutinized—as William Conway suggested, “Helping New York six-year-olds to learn about African monkeys may not help African monkeys” (Conway, 2007, 14). Zoo and aquarium educators are now more than ever questioning their role and the relevance of their work, to be more effective. The challenge is to ensure that visitors’ needs for animal sightings and information are met, while achieving the broader conservation education goals of the facility. It is clear, therefore, that education in zoos is moving beyond simply helping visitors to learn facts about animals and is increasingly focusing on more relevant outcomes, such as inspiring care for nature and encouraging behavior changes that support conservation and a more sustainable lifestyle (Gusset and Lowry, 2014; Sterling et al., 2007).

It is also interesting to note that there has been a shift in the focus of targeted conservation behaviors, with a new emphasis on actions that can be undertaken locally. Previously, in many cases the only “action” asked of the visitor at a zoo or aquarium was to sign a petition or to donate money to save forests, elephants, pandas or some other charismatic megafauna. This made it difficult for visitors to connect their daily conservation behavior in their local environment with the actions needed to “save the panda” or other animals who lived in remote protected areas or far off countries. Increasingly the links between actions at home and impacts in the wild are being realized, strengthening the message that conservation action can start at home, and that, through appropriate pro-environmental behavior, each visitor can contribute to conservation of animals and the environment. With millions of visitors each year (Gusset and Dick, 2011), the role that zoos and aquariums can play in facilitating such change is now more critical than ever.

Evolution of Interpretation Techniques

As animal exhibits and enclosures have changed to become more representative of natural habitats, so too have the educational techniques used for presenting visitor information within exhibits. Table 1 summarizes process of evolution that has taken place in relation to exhibit types, education techniques, strategies and goals.

These changes are clearly evident in interpretive signage in zoos and aquariums. Signs have evolved from simple labels displaying the scientific name of an animal, to enormous panels crammed with information, to more recent styles with a minimum of “layered” content arranged around themes and messages and presented in an entertaining and informal manner (Fig. 1) (Moscardo et al., 2007; Serrell, 1988). To facilitate changing educational objectives, techniques for zoo and aquarium interpretation now include better use of technology in the form of touch screens, mobile phone tours and apps (O’Connor, 2010). Recently

Table 1 Evolution of animal exhibits, education techniques, strategies and goals (extended from WAZA, 2005).

<i>Animal exhibits</i>	<i>Educational techniques</i>	<i>Education strategies</i>	<i>Education goals</i>
1. Cages/tanks 	Taxonomic labels, animal rides	Passive	Inform
2. Naturalistic dioramas 	Animal shows, content rich interpretive signage	Instructional Teacher focused Behaviorist	Teach facts about animals and diversity
3. Ecosystem/Multi-species exhibits 	Interactive activities, videos, minimal interpretation	Learner focused Meaning making	Engage, stimulate and inform visitors about animals and generate concern for animals
4. Immersion exhibits 	Mobile phone tours and apps, touch screens, Websites and animation	Constructivist Conservation psychology	Inspire and empower environmental behavior Issues based content
5. Extending the visit 	Websites, social media	Reflection on action and general call to action	Encourage long term environmentally responsible (conservation) behavior
6. Action campaigns	Targeted media campaigns, focused actions	Social science, behavior change theories	Change specific behaviors amongst visitors and a wider public

research has shown that the impact of the visit can be extended beyond the physical time spent at a zoo or aquarium through the provision of post-visit action resources that utilize a range of means to reach visitors after their onsite experience (Ballantyne and Packer, 2011; Ballantyne et al., 2018b; Hughes et al., 2011).

As a further development, an increasing number of zoos and aquariums are now undertaking campaigns to support very specific visitor behavior changes (Dunstan et al., 2016; MacDonald, 2015; Mann et al., 2018; Pearson et al., 2014). In some cases multiple zoos are running campaigns that target similar environmental threats, e.g., palm oil or plastic pollution, and require similar visitor behavioral responses. Such partnerships can then build support at a wider community scale. Collectively these campaigns have potential to reach a tipping point of conservation action with respect to policy, regulatory or market changes (Dunstan et al., 2016; Spring, 2018). For example, the sustainable seafood and palm oil campaigns run by multiple zoos, aquariums and other

partners point to the power of collective action, sometimes called supply-chain activism (Barongi et al., 2015). When visitors across many zoos/aquariums refuse to eat seafood that has been harvested unsustainably or only use products that contain sustainable palm oil, they have a combined significant impact that eventually leads to the legislative and social changes required for long term sustainable business and personal practices.

Zoos and aquariums are well placed to initiate behavior change campaigns or provide support to existing campaigns. As staff in zoos and aquariums are connected to individual animals, species or ecosystems, their passion and knowledge about the threats to those animals gives them a strong motivation to start a campaign. Zoos and aquariums also have easy access to people who specialize in communication—in their education or marketing departments, easy access to thousands of visitors, and the ability to connect people to animals. Feelings of connection to an animal or species have repeatedly been found to influence decisions about behavior (Clayton et al., 2009; Mann et al., 2018; Saunders et al., 2006). The following section provides further details on some of the behavior change campaigns that have been initiated by zoos and aquariums, and some of the results that have been achieved.

Zoos and Aquarium Action Campaigns

Some zoos and aquariums have embarked on ambitious campaigns with clear calls to conservation action in relation to issues such as seafood, palm oil, domestic cats, mobile phones, plastics and climate change—brief examples of these are presented below.

Seafood

Some of the earliest conservation action movements by animal care facilities came from aquariums who launched bold campaigns to change seafood consumption from unsustainable to sustainable species (those better able to survive fishing pressure). The first aquarium-based seafood consumer campaign was initiated by the Monterey Bay Aquarium in 1999 (Fig. 2). Subsequently, over 20 seafood campaigns have been initiated by aquariums, zoos and partnerships between such facilities and other organizations (nonprofit organizations, NGOs, restaurants or retail outlets). Research into the effectiveness of the Monterey Bay Seafood Watch campaign in 2003 and 2004 revealed that over 2 million pocket guides had been given to visitors and that for 76% of the study participants, the pocket guide had influenced their choice of seafood purchased (Kemmerly and Macfarlane, 2009). Recently, the Monterey Bay Aquarium has been able to use its position as a trusted voice for ocean conservation to directly influence the development of ocean policy (Spring, 2018).

The South African Sustainable Seafood Initiative (SASSI) is managed by WWF-SA with local aquarium partners. Research has revealed that 27% of respondents who collected a SASSI card during a visit to uShaka Sea World noted that they were still using the card 6 months after their visit (Mann et al., 2014b). Despite the criticism of seafood awareness campaigns (Barendse et al., 2018; Jacquet and Pauly, 2007), it is clear that collectively these campaigns have changed regional fishing practices and have encouraged increasing numbers of seafood retailers, distributors, food service companies and chefs, to utilize sustainable seafood options (Barendse et al., 2018; De Vos and Bush, 2011; Hallstein and Villas-Boas, 2013; Spring, 2018). The maturation of the sustainable seafood movement, the role of the movement in policy development and the rise of seafood awareness campaigns in Asia should address some of the criticisms that have been leveled against current conservation awareness campaigns (Barendse et al., 2018; Jacquet and Pauly, 2007; Spring, 2018).

Fig. 2 The Sea Food Watch Campaign prompt card. Monterey Bay Aquarium in the USA was the first aquarium to initiate a seafood campaign.

Palm oil

The clearing of virgin forest for palm oil plantations has had a devastating impact on biodiversity and particularly animals such as orang-utans in many tropical countries. Several zoos have tackled this issue through a range of consumer campaigns. The most robust evidence of the impact of such a campaign comes from Zoos Victoria's 2009 *"Don't Palm Us Off"*—a campaign that sought to raise awareness about the issue of palm oil and galvanize the public into action to reduce future deforestation. Visitors to Melbourne Zoo were engaged in the issue of palm oil both on-site (orang-utan exhibit signage, a 1-min video, wallet cards and petition cards to sign) and off-site (national media, social media, the zoo website, an on-line petition and downloadable fact sheets) (Fig. 3). Over 160,000 people signed a petition for mandatory palm-oil labeling of products, and significant increases were noted in relation to visitors' knowledge, positive attitudes towards orang-utans, and self-reported avoidance of products containing palm oil (Pearson et al., 2014). Importantly, the campaign contributed to changes in palm oil use amongst several major companies and led to changes in Australian legislation with respect to labeling (Banks and Dunstan, 2014). Several other zoos in Australia and New Zealand have adopted the *"Don't palm us off,"* campaign while in other regions, zoos have initiated their own "palm oil" campaigns. In the United Kingdom, Chester Zoo tackled the palm oil issue as a community driven campaign and is on course to help make the city of Chester the world's first sustainable palm oil city. In the United States, Cheyenne Mountain Zoo has designed a mobile application that helps consumers to select products made from sustainable sources of palm oil. Formal evaluation of these latter campaigns on behavior after a visit is not yet available).

Domestic Cats

To address the negative impact of domestic cats on indigenous fauna in New Zealand, Wellington Zoo initiated a campaign (*Cats inside at Night*) that encouraged visitors to keep their cats indoors during the night (MacDonald, 2015). Six weeks after their visit, 70% of respondents reported bringing cats inside at night, with over half attributing this behavior to the zoo messaging (MacDonald, 2015).

Mobile Phone Recycling

To address habitat loss through coltan mining in gorilla habitat, Zoos Victoria's *"They're calling on you"* campaign encouraged visitors to recycle their mobile phones. In less than a year the campaign resulted in more than 10,000 phones being diverted from landfill and raised over \$14,000 (Lowry and Gray, 2009). At least 13 other zoos and 100 community groups have also joined this campaign.

Balloons

After studies showed the enormous impact of balloons and balloon clasps on marine life (Lavers et al., 2014), Zoos Victoria decided to launch a campaign titled *"When balloons fly,"* that calls on the community to commit to "blowing bubbles" at special occasions rather than releasing balloons (Fig. 4). This campaign utilized on-site messaging, special educational programming, off-site partnerships with businesses, councils and festivals, and social media, as well as a highly publicized "World Record" bubble blowing event (McLeod et al., 2018). Over 130,000 visitors pledged to blow bubbles rather than release balloons and over 180 organizations committed to wildlife-friendly alternatives to balloons. Evaluation 12 months after the launch of the campaign revealed a significant decrease in the self-reported likelihood of using balloons (McLeod et al., 2018).

Fig. 3 The orang-utan is the icon associated with many of the palm-oil campaigns.

Fig. 4 The “When balloons fly” campaign launched by Zoos Victoria in Melbourne has changed the practices of many celebrations in Australia.

Evaluating Zoo and Aquarium Impacts

It is important for zoos and aquariums to actively measure their impact and identify the factors that influenced the impact. Quantifying the impact of behavior change campaigns can be difficult, because the rapidly increasing levels of public awareness of various environmental issues makes it difficult to tease out the contribution of any one intervention. Zoos and aquariums do not operate in a vacuum but contribute one piece to an enormous puzzle of public awareness-raising. More innovative methods are needed to identify the tipping points to action and to clearly determine which interventions are most effective, and what it is about those interventions that make the greatest impact on the public.

Quantifying the impact of a general visit to a zoo or an aquarium on visitors’ environmental behavior can be even more difficult. Unlike focused campaigns, where the visitor is clearly being asked to do something specific, general zoo or aquarium visits may be targeting a range of environmental behaviors, as well as the knowledge, attitudes and dispositions that act as the precursors to these behaviors. While measuring the ultimate goal (e.g., decreasing a threat to a species or an ecosystem in the wild) is a long term endeavor, steps towards achieving those goals can be measured (Dunstan et al., 2016). Social impact measurements are varied and include:

- counting the number of people taking the target action (e.g., number signing a petition; number of emails sent to companies),
- measuring changes in knowledge and attitudes (e.g., increased understanding of the threats),
- measuring self-reported behaviors after the visit (e.g., post visit evaluation results),
- assessing changes within local or regional communities or markets (e.g., actual number of companies committing to better practices; changes in legislation; and/or growth in market shares for sustainable alternatives), or
- assessing changes at a policy or governance level (e.g., changes in policies or regulations) (Dunstan et al. 2016).

Research by Ballantyne et al. (2011a) in four different wildlife tourism attractions found that four months after a visit, 5% of respondents reported having questioned their values or changed their personal attitudes; and 7% reported some new actions they had taken in support of the environment, as a result of the experience. Interestingly, an analysis of visitors’ memories four months after their visit (Ballantyne et al., 2011b) suggests that while factual information about the animals may have been forgotten, information about the dangers faced by the animals, particularly the threats posed by human actions, were remembered and aroused feelings of protectiveness and concern. This led visitors to think about their role in environmental care and supported a sense of personal responsibility, which in some cases resulted in direct action.

Smith et al. (2008) found that 26 out of 38 people (68%) who were followed up by phone six months after a zoo visit, indicated that they had started an action or increased their commitment to an action to protect birds and their habitats. Vernon et al. (2012) found that 55% of respondents who encountered conservation information or experiences during their visit retained and translated these encounters into personal actions that persisted for up to six months after the visit. Mann et al. (2018) found that more than a year after their visit, 49.4% of respondents could give an example of conservation action that they attributed to their visit. Further, these latter two studies revealed that not only do visitors take action after a visit, but that they communicate with others and inspire them to take action too (48% and 21% of respondents respectively). However, other studies have noted little or no impact on the conservation behavior of visitors after a visit (Adelman et al., 2001, 2000; Ardoin et al., 2015; Dierking et al., 2004).

These somewhat contradictory results highlight the fact that measuring post-visit conservation action is difficult (Stern, 2000), requiring innovative methodology and an open mind (Moss and Esson, 2013). It is often the case that very different estimates of impact are obtained, depending on the way the question is asked. Developing standard techniques for measuring impact, that are shared across sites and repeated across time, may be one way to overcome this problem in the future.

Factors that Lead to Success

The results of several research studies, as well as the application of theory, provide practitioners with some guidance on how to design behavior change campaigns and general visitor experiences that are successful in encouraging and supporting conservation action. In relation to behavior change campaigns, for example, Community-based social marketing theory (McKenzie-Mohr and Smith, 1999) suggests that an effective campaign should:

- select the target behavior with care (have a good understanding of the desired behavior, its impact on the environment, what motivates the behavior, and barriers to the behavior);
- rely on more than simply information (use emotional connections as well as information);
- reinforce the message both during and after the visit (multiple messages about the same behavior, website, downloadable information, fact cards);
- use prompts or triggers (pocket guides, consumer cards, post cards);
- keep visitors involved (post-visit follow-up, information, thank-you messages); and
- mobilize and support early adopters (identify role models who could model desired behavior) (Dunstan et al., 2016; Kemmerly and Macfarlane, 2009; Mann et al., 2018).

Research has demonstrated that the following factors also contribute to the success of a campaign:

- providing opportunities to connect emotionally with an animal;
- ensuring that information is credible and specific, but providing more than just information;
- repeating the same simple message repeatedly;
- having a clear call to action;
- empowering visitors with appropriate tools (cards, petitions, etc.);
- including a prompt to trigger recall;
- providing opportunities to reflect on the requested action;
- reducing barriers to action where possible;
- providing links between the action and daily life;
- understanding that each campaign contributes to a bigger conservation action; and
- being able to change as the situation changes (Dunstan et al., 2016; Kemmerly and Macfarlane, 2009; Mann et al., 2018).

Ballantyne and Packer (2011) conceptualize the factors influencing the impact of general zoo and aquarium visits as an ongoing process of interaction between pre-visit, on-site and post-visit factors.

Pre-visit Factors

Pre-visit factors focus on the previous experiences, beliefs and motivations that visitors bring with them to zoo or aquarium. Understanding visitors' motivations, for example, and their influence on onsite learning and post-visit behavior is critical to an understanding of the process and impact of free-choice learning (Ballantyne et al., 2011a; Falk, 2009). Although it may appear that it is beyond the control of zoos and aquariums to influence pre-visit factors, it has been noted that how a site is marketed can influence visitors' motivations and expectations (Ballantyne et al., 2011a; Mann, 2016). Thus, zoos and aquariums may be able to enhance their impact by promoting themselves as institutions for conservation education.

Another pre-visit factor that has received recent attention is visitor values. Ballantyne et al. (2018a) demonstrated that visitors' personal values influence the extent to which they are able to be reflectively engaged during their visit, with consequences for their post-visit environmental behavior. They concluded that using a values-based approach to visitor interpretation, which acknowledges individual differences in broad life goals and ways of seeing the world, and intentionally builds on and engages with these perspectives, would enhance the impact of a zoo or aquarium visit.

On-site Factors

Some studies have focused on identifying the characteristics of on-site interpretation and visitor experiences that impact on visitors' engagement and behavior change outcomes. The Monterey Bay *Inspiring Ocean Conservation* project (Vernon et al., 2012), for example, found that conservation-focused exhibits and presentations, discussions with a staff member, and taking home a Seafood Watch pocket guide supported an interest in and desire to take action. Similarly, the 'Penguin Promises' program at uShaka Sea World in South Africa (Fig. 5) (Mann et al., 2018) found that allowing visitors to select a "promise to the penguins" from a range of conservation actions was effective in encouraging visitors to increase their engagement in environmentally responsible behaviors. In contrast, many facilities have expended effort in the creation of innovative and attractive exhibits that highlight climate change. However, when these exhibits fail to provide clearly defined calls to action, there is little evidence to support their impact.

Providing visitors with an opportunity to reflect on their experience during their visit has been shown to enhance environmental learning and subsequent environmental behavior (Ballantyne et al., 2011a; Mann, Ballantyne, and Packer, 2017). While having fun with family and friends will always be one of the primary motivations to visit a zoo or aquarium (Ballantyne et al., 2007; Linke and Winter, 2011; Morgan and Hodgkinson, 1999; Packer and Ballantyne, 2002), it is increasingly evident that visitors now see such

Fig. 5 Visitors to uShaka Sea World, Durban, South Africa make a “Promise the Penguin” on a hand-written postcard.

facilities as trusted voices for conservation (Boyle and Mott, 2009) and that they expect zoos and aquariums to provide them with information on how to contribute to conservation efforts (Ballantyne and Packer, 2016; Roe et al., 2014). Since the concept of reflective engagement (cognitive and affective processing of an experience) was introduced in the zoo context (Ballantyne et al., 2011a,b; Packer and Ballantyne, 2013), a number of studies have provided evidence of the importance of reflective engagement in supporting behavior change (Hughes et al., 2011; Pearson et al., 2014).

Post-visit Factors

It has been argued that, in order for zoos and aquariums to really influence the behavior of visitors when they return home, it is essential that conservation messages be reinforced through the provision of post-visit resources (Ballantyne and Packer, 2011; Hughes, 2011; Hughes et al., 2011). Working out how to best reach the visitor after the experience is becoming progressively more important and, as such, research designed to optimize the use of post-visit resources is increasingly being undertaken. These resources could include learning materials in the form of brochures, newsletters, websites, e-mails and social media. Research indicates that the provision of such resources can encourage visitors to participate in environmentally sustainable actions and enhance their attitudes towards wildlife (Ballantyne et al., 2018b; Hughes et al., 2011).

Here are just a few examples of post-visit websites available to support visitors' conservation action at home:

<https://www.zoo.org.au/dont-palm-us-off/>

<https://www.zoo.org.au/balloons/>

<https://www.seafoodwatch.org/>

<https://penguinpromises.com/>

<http://www.cmzoo.org/index.php/conservation-matters/palm-oil-crisis/>

Conclusion

While it is clear that there have been advances in research that evaluates the impact of a visit to a zoo or aquarium on visitors' subsequent conservation action, this field is still new and requires considerable attention (Khalil and Ardoin, 2011; MacDonald, 2015; Mellish et al., 2019). Research has shown that many zoos and aquariums are inspiring their visitors to undertake more environmentally responsible behaviors and that these behaviors can sometimes be sustained during the months if not years after their visit.

However, given the difficulties associated with measuring behavior change, the small number of studies and the many zoos and aquariums undertaking behavior change campaigns there remains great scope for both case studies and theory-based research to provide further evidence of the effectiveness of zoos and aquariums in encouraging conservation action, and to provide guidelines to enhance this impact.

Abstract

In this essay I review perceived beneficiaries of dominant environmental policies versus the losers of such policies. Specifically, a conflict between the conscious environmental bourgeois and the unconscious environmental proletariat. Therefore, I peer review of Karl Popper's piecemeal engineering in relation to the environment; a thought which detects social problems and evaluates public policies in bit and pieces for socially induced transformation, and, in this case, its application to environmental management. Bearing in mind that public institutions, both national and international, are controlled by the environmental bourgeois, I propose that genuine environmental management is imposed on the environmental proletariats, and such duties must be anchored primarily upon the philosophy of cooperatives. Given the foregoing, I advance for a universal piecemeal approach, built on cooperative principles and values for holistic environmental management. This, I defend, is the most significant, radical and realistic mechanism to check-mate further depletion of the earth and serve as a catalyst for the actualization of sustainable development.

Introduction

Our environment is the truest unifying factor available to all of humanity. This is anchored on its readiness to serve humankind irrespective of our divides. We all exercise the freedom to breathe the air, use the water, and explore the land. Though, humans are born free, but everywhere they go, they are also constrained. In other words, the human experience is subject to a variety of forces, which could be social, political, or economic in the environment. Thus, humankind in the bid to improve living conditions have employed some measures that have devastating effects on the environment, for instance, some production or manufacturing processes have triggered ozone depletion and climate change, both of which have contributed to poverty in extreme cases. These environmental challenges further widen the existing divide among the countries of the world particularly in the light of the globalization process.

Divides are a constant feature in the relations that exist in the community of states be it at the regional or sub-regional level although the emphasis gains more publicity in the rather narrow north-south/core-periphery/rich country—poor country classifications. The core substance of divides remain basically within the Marxian “haves, and the have-nots,” bourgeoisie-proletariat divides that are replicate across our universe. The contest between the two has many principal fronts, one of which is the use of the environment; a subject that rears enormous conflict on the economic, social and political fronts. Rising from these is the policy question of “which public policy most appropriately suits the environment, not just for gains, but sustainable development?”. The bourgeois characteristically controls the means of production and consciously influence environmental policies to support their interest. On the contrary, the proletariats, are often pre-occupied with the search for daily bread, thou conscious of their predicament, but not conscious in their drive at influencing policies for remedies.

A way forward is to conceptualize a common ground among environmental activists. Therefore, I will review the ideals of cooperativism that would birth a hybrid of Cooperativism; one that embraces the philosophy of cooperatives, cooperation and solidarity economics, and Karl Popper's philosophical thoughts, especially his concepts of piecemeal social engineering, a thought

which detects social problems and evaluates public policies in bits and pieces for socially induced transformation, in this case, its application to environmental management.

This bears in mind that the bourgeois class, in the present discuss, the environmental bourgeois, controls public institutions across national and international boundaries. Consequently, neither Karl popper's piecemeal social engineering approach, nor cooperativism will be competent in their separate capacities to address contemporary environmental challenges, thus the literature suggest an admixture of both is presented as the most significant and realistic mechanism for environmental management and sustainable development.

Conceptual Clarification

Environmental Management

The 21st century has been of massive industrialization, which entails enormous exploitation of the environment, from massive agriculture to feed the over 7 billion humans currently on earth, to natural resources exploitation with consequences such as gas flaring, and rechanneling of waterways, and further consequences such as water, land and air pollution. The trend has been phenomenal, rarely abated, instead ever increasing, all in response to socio-economic and political dictates across the states of the world. The most pertinent questions appears to be about sustainability, that is, using the environment in a way and manner that future generations are not left at risk.

The interplay of interest between the environmental positivist and their antagonist further brings to fore the importance of the use and management of the environment in relations to sustainable development. While the environmental positivist, which I regard as the environmental bourgeois made up of the world bourgeois class across all the state of the world would continue to canvass for further exploration of the earth, building their position on socio-economic and political exigencies and dictates, the environmental proletariats on the other hand continue to antagonize on the same grounds of socio-economic and political dictates, thou of a different variant, building their position on among others cultural protectionism and sustainable development.

Unbiased observation tells both divides have logical claims to the paths they so vigorously pursue. However, there are needs for a melting point that guarantees not only the best for today, but reserves a much better variant for the future. Thus mankind is faced with the puzzle of which variant offers the most adaptive management to the environment.

Cooperativism and the Environment

Cooperativism is the philosophy of cooperatives, cooperation and solidarity economics, and centers around the cooperatives, which are autonomous association of persons, united voluntarily to meet their common socio-economic needs through jointly owned and democratically controlled enterprises. This is closely linked to Ostrom's idea that common pool resources should be owned and administered by a collective institution. She further views the ownership and control of these resources by the commoners themselves as a better alternative to socialism, that is state control of resources and private enterprise system, both of which are hierarchical in nature and ultimately do not serve the interests of the commoners (Ostrom, 1990). Cooperatives are formed by people who use their products, and services. Though cooperatives vary in types, membership and styles, they all operate for the core objectives of members and the society, at doing these, they have been known to exhibit high level of adaptivity. Cooperative are guided by principles and values.

The Principles are:

- (a) Voluntary and Open Membership
- (b) Democratic Member Control
- (c) Member Economic Participation
- (d) Autonomy and Independence
- (e) Education, Training and Information
- (f) Cooperation among Cooperatives
- (g) Concern for Community.

The values are:

- (a) Self-help
- (b) Self-responsibility
- (c) Democracy
- (d) Equality
- (e) Equity and
- (f) Solidarity

Both principles and values contributed at making cooperatives and the more encompassing philosophy of cooperativism an increasing socio-economic, and political mechanism across the world, with profound applications into government and governance especially the various sub-fields such as trade education, health, agriculture, and infrastructural development. In furtherance to

these, cooperatives, have proved equally relevant in the sphere of environmental management. Wiskerke (2003), conceptualizes this phenomenon in the following words “within the domain of agriculture and rural development, self-organization and self-regulation emerges as a new model of rural governance. Environmental co-operatives are a promising expression characterized by new institutional relations between state agencies and agricultural communities, new social networks of trust at local level and the re-embedding of farming in its local, social and ecological context.”

Although Wiskerke (2003) treats cooperatives in environmental management from the viewpoint of agriculture and rural-urban challenges, the importance of cooperatives to environmental management thou encompasses agriculture and rural-urban challenges, and has a much larger scope. Perhaps in response to the above, Franchini et al. (2017), evaluates cooperatives in environmental management from the viewpoint of challenges of the anthropogenic, having identified international environmental politics and global governance as important pillars in this regards, the authors went ahead to posit “it is necessary to radically modified the institutional structure of cooperation based on international regimes; the transition from environmental politics to global governance.” Both instances affirm the importance of cooperatives in environmental management within the vertical and horizontal structures.

Karl Popper

Sir Karl Raimund Popper was born on the 28th of July 1902 in Vienna, Austria, he was an Austrian-born British philosopher who did many works on the natural and the social sciences. He contributed significantly to science, epistemology, and socio-political philosophy, especially with his antagonism of totalitarianism in all his guises as espoused in his works, specifically the 1945 epoch; His political thought resides squarely within the scope of “enlightenment rationalism and humanism” which buttressed his critique and condemnation of the “Closed Society” in favor of the “Open Society.” Further the condemnation of “Utopian Social Engineering” in favor of “Piecemeal Social Engineering,” and his disposition in favor of Minimalist Democracy as a panacea to defeat the hold of the bourgeoisie class on the modern state places his work in an enduring position for contemporary applications. Karl Popper’s philosophy is relevant to this review as it has proved to detect social and political problems and has shown capabilities to evaluate public policies in bit and pieces for socially induced transformation. Bearing in mind that although cooperatives have played significant role in sustainable development, emerging problems dictates the fortification of cooperative principles and value with other thoughts that have stood the test of time, such is Popperian philosophical thoughts, in this case in application to environmental management.

Main Focus

The gravamen of this work is the actualization of holistic environmental management for sustainable development through the strength of the cooperatives, or more precisely on the wheels of cooperativism. At doing this, the enormity of the bourgeois-proletariat relationship is well emphasized. Bearing in mind the phenomenal of the clash of classes, especially as it relates to the formulation and implementation of environmental policies, the blend of the vertical and horizontal links in the use of the environment, the advantaged position of the beneficiaries of dominant environmental policies and the disadvantaged position of the losers in environmental use and management. It becomes apt, to attempt a hybrid of two largely acceptable developmental philosophies: Cooperativism and Popperism in relation to the environment. From the foregoing a universal piecemeal approach, as discussed by Popper (1945), built on cooperative principles and values is advanced to check-mate not only the further depletion and degradation of the environment, thus achieving the goal of environmental sustainability which is part of achieving sustainable development.

Popperian-Cooperativism and the Environment

The very essence of Popperian-Cooperativism is to supplement the ideas of cooperatives with the thoughts of Karl Popper. It is expected that the hybrid produced will offer a more effective and efficient mechanism for sustainable development through holistic environmental management. Based on this projection, Popperism is related with each of the seven principles of cooperatives, which I review below.

Voluntary and Open Membership

According to the ICA (1995) cooperatives are voluntary organization, open to all persons able to use their services and willing to accept the responsibilities of membership, without gender, social, racial, political or religious discrimination. This principles require membership of cooperatives be made open to all prospective members, and restrictions should be kept at the barest minimum. Chukwu (1990); “the open door advantage of cooperative openness is that the open door policy makes good philosophy, and also promotes the spread of the cooperative movement across countries and the world, thus making the benefits of membership good because of the process of integration.”

Voluntary and open membership principles of cooperatives, examines the voluntariness and openness of organizations that formulates and implements environmental policies. These bodies could be sub-national bodies, national bodies, regional bodies, continental bodies, and international bodies that operates at the inter-continental levels.

These bodies set out to do the following among others:

- (a) assessing the state of the environment
- (b) evaluating the state of the environment
- (c) controlling the environment by various means such as law, regulations, protocols, conventions, incentives, moral persuasion, training, information campaign etc.

In our contemporary world, divides along socio-economics and politics characterizes the membership of such organizations. At the sub-national and national level, non-membership of religious faith, economic standing, educational attainment, non-membership of a particular political party, ethnic affiliation etc. could prevent qualified and willing persons from the membership of relevant institutions that formulate and implement environmental policies. This is a reflection of the realities of existences in many developing countries. There are also versions of this at the regional, continental and inter-continental levels, much as the economic and political giants dictates the pace for less viable states. It is either membership is not "open" or voting patterns are unequal, at other instances, bourgeoisies members "instills" their positions on membership and voting on the sheer strength of their economic and political power.

This bears elements of totalitarianism, as it is against freedom and individualism, it bends toward the Popperian "Closed Society." Popper argued, based on his observation of ancient Greece, that reactionary forces would always be uncomfortable with the rapid changes that characterizes an "Open Society." He posited that closed societies are anti-democratic, marked with rigid class hierarchy, and made no significant contribution to arts and scientific development. Institutions saddled with environmental management should be largely scientific, although their melting point with politics cannot be relegated, but it requires openness, inclusivity and equality. Based on this, they should bear more of the ingredients of the "Open Society." Thus the Popperian "Strain of Civilization" should be encouraged with the utilization of the cooperative principle of Voluntary and Open Membership, while it should be employed for the abolishment of what Popper described as "tribalism" (Open Society Vol. 1).

Democratic Member Control

Cooperatives are democratic in character. They are organizations controlled by their members. These members participate actively in the policy processes. Elected representatives are responsible to the membership. This principle promotes what is otherwise called "economic democracy in action." Since cooperatives were established for the restructuring of the society, especially by way of inclusion, the idea that each person hold a vote regardless of his economic standing goes to support the cooperative values of equality and equity.

According to ICA at its 1966 Congress, Co-operative societies are democratic organizations. Their affairs should be administered by persons elected or appointed in a manner agreed by the members and accountable to them. Members of primary societies should enjoy equal rights of voting (one member, one vote) and participation in decisions affecting their society. Sustainable development, in this case the interest of all in environmental issues are best achieved through meaningful participation of all divides in the policy process.

Democratic politics as espoused with Popper's characterization of the "Open Society" should be the hallmark of environmental management. He argued that societies are more real than the individuals that lives inside of them (Open Society Vol. 180), by consequence he meant that the truest strength or weakness of a society resides in the coming together of her people, preferably on equal yokes. In 2014 the World Resources Institute (WRI) in one of its research works on the viability of democratic principles to environmental management brought back to fore the once proposed five-dam project on the Baker and Pascua Rivers in Patagonia, Chile. WRI posits that while the hydropower was projected to possess the capacity to produce 2650 M watts of electricity, on the contrary the project would flood about 23 mile² of wildlife, with adverse effect on the environment, local culture and economy of the region. The project was successfully opposed by a coalition of over 70 organizations from within and outside Chile. Important is the fact that citizen's agitation was primary in the opposition.

Popper further posits against what he described as "minimalist democracy." He rejected the question of "Who should rule?". Rather he proposed the question of "How can we so organize political institutions that bad or incompetent rulers can be prevented from doing too much damage?". He viewed democracy from a pragmatic angle on a people oriented institutional design. Popper proclaimed that there is nothing intrinsically valuable about democracy until it is built on the sovereignty of the people in a model of democratic member participation.

The Application of Democratic Principles Will Instill Into Environmental Management Fundamental Rights which are Built on the Tripod of:

- (a) Access to Information,
- (b) Public (inclusive) Participation
- (c) Access to Justice.

This can be espoused further with the following assertions:

Firstly, public and private initiatives on environmental exploration should be open to the public forehand. Information; such as development project plans, environmental impact assessment etc. should be readily available for not only public consumption, but to all divides.

Secondly, there should be more discussion at equal pedestrian between governments, governments and communities, government and the business community (communities), companies and communities, communities and communities on environmental use and management.

Thirdly, is access to “real justice” and not justice from the viewpoint of the stronger party. This should include both litigation and Alternative Dispute Resolution mechanism, it should guarantee for all parties quantum of merit and effective means of enforcement.

Member Economic Participation

According to the third principle of cooperatives; members are to contribute equitably, and democratically control the capital of their cooperatives. It spells out the responsibilities of members to their cooperatives, especially as regards finances. Although this principle starts with the emphasis on money management, its core values remain the socio-economic stability and upliftment of members, thus both the cooperative and its finances are structured for the needs of members. Cooperatives are capitalized through the pooling of funds, while this imposes on the association that it exists and operates for the benefit of all members and not just a section of its membership.

Inclusion in environment management is one, participation is another, and perhaps of more importance. Popper’s contention against “utopian social engineering”; a model that seeks to administer the society in accordance with a definite blueprint, where ultimate human ends such as perfect justice, equality, freedom, happiness and fulfillment are fully realized. Rather he argued in favor of the “piecemeal social engineering,” a small scaled model that focuses on one institution at a time and seeks to eradicate sadness, unemployment, poverty, environmental degradation etc. He posits that “utopian social engineering” imposes on the people totalitarianism, as such it must be substituted with another model where men and women are not just pawns in the social system, but are *economic participants* in a new society, (*Poverty of Historicism*, 70).

Institutions involved with environmental management will always have members, but the quality of the participation of members is primary, especially the economic participation of members. On the international stage, non-payment of due has been a major drawback on the activities of such organizations, the revenue aspect of budgetary proposals often fall short of projection due largely to unpaid financial dues on the part of some members. Often, the defaulters lay claim to inability to pay, citing poor financial position or poor standing in the Human Development Index (HDI). However, sub-management of the environment, which is a likely consequence of financial default of such member states, could lead to environmental degradation and consequently disasters which portend further compound economic and financial woes. Non-financial participation on the part of some country under any guise is simply an affirmation to the dominance of the environmental bourgeoisies, as states from the global north have continued to showcase themselves as consistent financial members. Non-financial membership sometimes excludes such members from core decision making roles, thus further widening the gap between divides, ultimately, it confers more economic and political powers to persist in domination on the financial members.

Autonomy and Independence

The fourth principle of cooperatives states “Cooperatives are autonomous, self-help organizations controlled by their members. If they enter into agreements with other organizations, including governments, or raise capital from external sources, they do so on terms that ensure democratic control by their members and maintain their cooperative autonomy.” This principle dwells more on the fundamentals of identity. Cooperatives are to serve their members and not to serve any ideology e.g., politics, religion etc. Institutions saddled with environmental management are to strive toward independence and autonomy, this becomes a task in view of the nature of the support system upon which these institutions were created and currently survive, they are institutions of state(s) and are financed by same.

In Popper’s latter editions of *The Open Society and Its Enemies* he grew more critical of direct state intervention to tackle socioeconomic challenges. Instead the preferred amendments to laws toward less state, but more people oriented approaches. He posits that direct intervention by government is always to the advantage of the state and the elite class, this is to the detriment of those on the other divide. A way out of this, according to Popper is to promote and sustain autonomy and independence in both the policy and legal frameworks.

Most of the institutions involved with environmental management, public or private depends on patronage from either the public or private sectors, and in some cases both to survive. On the other hand, these patronages are a reflection or extension of ideologies, which in turn demand loyalty from institutions they patronize. If this continues, the policy process will continue to be influenced with extraneous interest, which will be inimical to the independence and autonomy of institutions involved with environmental management.

The imperative of avoiding this unpleasant circumstance, is at the core of the humanist value required in the management of the environment. The environment cannot be managed on sectional interest, else it becomes a business from the economic perspective or instrument of domination from the political perspective. Consequently, there arises the strict requirement on environmental management to operate on firm, uncompromising humanist principles, which can only be built on austere approaches that are enshrined in the fourth cooperative principle and the values of cooperatives.

Education, Training and Information

Karl Popper's attempt to critic the "Utopian Social Engineering" concept and in its stead champion the "Piecemeal Social Engineering" theory can only be appreciated in an atmosphere of enlightened minds, according to Corvi (1997) that is in a society with viable and consistent system of education, training and information that is devoid of totalitarianism and centralism. A society, with a social democracy that places education as an integral theme of human rights. Popper posits that "human knowledge grows and changes overtime, and knowledge in turn affects social events" (Internet Encyclopedia of Philosophy, Pg. 8). To Popper, the capacity to gain the knowledge to survive the future is of essence if societies must be kept "Open."

He further contends "change the conditions and the trend may alter or disappear. A trend toward greater knowledge and freedom could be sustained or disrupted, which could facilitate an "Open" or a "Closed" society" (Conjectures and Refutations, 339). The tendency is very high that humans will function better if we understand the theory and practice of issues and circumstances around us, when we appreciate the value behind conflicting theories and practices involved with our daily thoughts and activities. The fifth principle of cooperatives centers around cooperatives as mechanism for improved humanity through education, training and information. It states (ICA, 1995) "cooperatives provides education and training for their members, elected representatives, managers, and employees so they can contribute effectively to the development of their cooperatives. cooperatives inform the general public-particularly young people and opinion leaders about the nature and benefits of cooperation." According to the EPA (2019) environmental education in all its ramification can best be achieved only on the platform of the cooperatives. Environmental education is one, objective utilization of the lessons from the concept for holistic environmental management is another.

Integration of cooperativism into environmental education builds into the various institutions involved with environmental management relationship that raises sustainable achievements through the transformation of such institutions into the appreciation of values in diversity. It instills into the policy process socio-economics and political solidarities, which are essentials for holistic environmental management. Environmental education empowers individuals, groups and institutions to properly explore environmental issues along thoughts and activities for environmental sustainability. It seeks to develop deeper understanding of the environment across divides.

Some of the components of environmental education are:

- (a) Awareness and sensitivity
- (b) Knowledge and understanding
- (c) Promotion of positive attitudes
- (d) Skills development
- (e) Improved inclusion.

Environment education encompasses, both environmental training and information.

Benefits of Environmental Education as the Following:

- (a) Imagination and enthusiasm are heightened
- (b) Learning transcends the formal settings
- (c) Tolerance and understanding are supported
- (d) Integration of sub-national, national and international standards
- (e) Biophobia and nature deficit disorder declines
- (f) Communities are strengthened
- (g) Responsible actions for environmental management becomes more acceptable.

However, all of the above becomes sub-utilized until competent approaches are employed. When member of environmental management institutions are educated, and training and information are in accordance with the cooperative model and Popperian thoughts, personnel saddled with responsibilities become better equipped at contributing effectively at driving such institution toward holistic environmental management.

Cooperation Among Cooperatives

According to (ICA, 1995) "Cooperatives serve their members most effectively and strengthen the cooperative movement by working together through local, national, regional and international structures." The environment is a single unit with broad spectrum, it is segmentalized by human use and projected use. As much as our interest has given us a mental division of our environment, even with the exploration of the earth often carried out from isolatory thoughts about other places, the environment remains a circle. It binds human actions and reactions across different spectrums.

An offshoot of this is the not so robust linkages on environmental management between individuals, groups and institutions. Take for instance in Ibadan, Nigeria; some individuals in their rather uncooperative conception of waste disposal simply go out at night to dump heap of refuse from their home by the roadside, or dump same on waterways during the rainy season with the intention that the rain would wash it away. In similar vein are the activities of some persons in the Niger-Delta region of Nigeria, who in their quest to illegally access crude petroleum burst huge pipelines conveying the product, after obtaining the desired quantity, but leave the remaining to spill into adjacent farmlands, rivers and the natural environment because they lack the capacity

to repair the bursted pipelines. On the larger scale is the shared environmental concern between India and Pakistan, or India and China, some multinationals and host communities etc., all culminates to challenge the environment and its management.

There are always activities on environmental management, with high profile claims of best practices, but there remain a huge vacuum for the redress of environmental degradation, global warming, desert encroachment etc. as support for this assertions. What is lacking is the synergy of activities, or in another word, solidarities among the various activities. Earlier in this work, the importance of solidarities within communities, and institutions involved with environmental management was canvassed. The next frontier canvassed is the solidarity among the various solidarity built initiatives. Each working for itself, for the other and with the other, from the local, national to the international, along horizontal and vertical lines. This is the crust of the sixth principles of cooperatives, "cooperation among cooperatives" in environmental management.

Concern for Community

This is the seventh and last principle of cooperatives, it encompasses all other principle and the values of cooperatives. According to the (ICA, 1995) "Cooperatives work for the sustainable development of the communities through policies approved by their members." Policies aimed at the sustainable development of communities and state should be based on policies agreed to by all the divides present within communities and states. These policies are to be in accordance with the "Piecemeal Social Engineering" as this Popperian philosophy emphasizes the real on small realistic scales with concentration on the truest needs of the community. While promoting the "Piecemeal Social Engineering," Popper introduced a concept he called "Negative Utilitarianism" to proffer answers to the question of "which of the problems of society is most urgent?" he responded that "human misery is the most urgent problem of a rational public policy." Cooperative philosophy has been employed the world over to address human miseries in different facets, e.g., poverty, illiteracy, access to health care, improved agricultural productivity, microfinance and in the instance case environmental challenges.

If the word "community" from the phrase "Concern for Community" is substituted for "environment" toward a better conceptualization of this work, then is safe to conclude that "if cooperative principles and values are agreed upon as management policies for the environment, actualization of sustainable development becomes more realistic."

Conclusion

This review has provided bold conceptualization of holistic environmental management with the use of cooperative principles and values. Bearing in mind the complex nature of man, especially as it involves economic, social and political interest in their various forms, and the different approaches often employed at protecting this interests, there was a further attempt to supplement cooperative principles and values with Karl Popper's philosophical thoughts (Popperism). Based on this, the various human divides, and their strands of input which had taken tolls on environmental management were identified for remedial and improvement to support sustainable development from an admixture of cooperative principles and value on the one hand, and Popperian thoughts on the other. It is hoped that this literature will be of immersed value for environmental management and sustainable development.

Abstract

Communication is a social process affecting human behavior, including both in-person and virtual interaction made possible by advances in technology. Social media communication allows users world-wide to connect with each other, engaging with shared content ranging from personal messages to news to entertainment. Anyone with a device and Internet access may engage with social media, and individuals, businesses, and public organizations are active users. Social media communication is utilized in the important domain of sustainability: Meeting present needs without compromising the ability of future generations to meet their needs. Sustainability activities are broad and include environmental, economic, and social initiatives at multiple levels. This article discusses key elements of social media, its use in organizations, its application within sustainability communication, and future challenges.

Communication is a social process affecting human behavior (Godemann and Michelsen, 2011). Individuals have always communicated with others: first through direct, face-to-face connections, then indirectly through images or the written word, and today through multiple channels and formats made possible by rapid advances in technology. Social media communication allows users world-wide to connect with each other, engaging with shared content ranging from personal messages to news to entertainment. With this shift to digital platforms, anyone with a device and Internet access may engage with social media. This global connectivity, in turn, allows for the creation of virtual networks and communities.

Social media communication covers a broad array of topics, and it is used by individuals, businesses, and public organizations. One steadily-growing domain addressed via social media is sustainability: meeting present needs without compromising the ability of future generations to meet their needs. Sustainability activities are broad and include environmental, economic, and social initiatives at multiple levels. This article discusses key elements of social media, its use in organizations, and its application to sustainability communication.

Background of Social Media

Social media is a broad term that refers to people interacting in online, multidirectional communication. It differs from traditional one-way communication by providing an interactive experience among participants, rather than a transmission outlet broadcasting information with no direct reaction or response (Kaplan and Haenlein, 2010; Joosse and Brydges, 2018; Saxton et al., 2019). Individuals, organizations, businesses, governments, and communities use social media, and the global availability of the Internet has supported this interactive communication. The world's population was about 7.6 billion in 2019, and over half the planet's inhabitants reported using the Internet regularly. Statista data indicate that on average, Internet users across the globe spent 135 min daily on social networks in 2019.

The rise of social media as a powerful communication tool has been rapid, reflecting the explosive increase in information available through major shifts in technology (Godemann and Michelsen, 2011). Kaplan and Haenlein (2010) highlighted the impact of Web 2.0, a term that describes how software developers and end-users have utilized the Internet as a platform to share and modify content in a participatory fashion; see also Fieseler et al. (2010). Social media usage worldwide has contributed to new exchanges of knowledge and different forms of virtual collectives.

The Pew Research Center, a nonprofit, nonpartisan data research center (www.pewresearch.org) began tracking social media engagement in 2005. At that time, some 5% of American adults used at least one social media platform (Pew, 2018); by 2018, 95% of North Americans engaged in social media use, and world-wide social media users reached almost 2.5 billion. This global engagement clearly offers immense potential for communication outreach in multiple domains. Social media market penetration varies by region and reflects the *digital divide*: global inequalities in information access. According to Statista data, North America and Northern Europe reported the highest penetration, at 95%, with significantly fewer users (51% and lower) in Central Asia, the Caribbean, and all regions of Africa.

The broad array of social media formats allows for information transmission, content sharing, and entertainment, and most communication is available instantaneously. Widely and rapidly sharing a social media *post* (text, image, or video) is called *going viral*. From a practical standpoint, social media is easy and inexpensive. While music and video streaming services may charge a subscription fee, the costs for social networking platforms are generally free to users because they are covered by advertiser support. For example, many popular YouTube videos cannot be accessed without first viewing a short advertisement from a corporate sponsor.

User Characteristics

Anyone with access to the Internet and a device (e.g., smartphone, tablet, or computer) can utilize social media, so its reach crosses demographic attributes and geographic boundaries. Social media was first embraced by young participants, but its audience now crosses the age spectrum, although younger users remain the most actively engaged. For example, Pew data (2018) indicated that the Instagram platform achieved 64% market penetration among American young adults (ages 18–29), compared to 21% of middle-aged users (ages 50–64). Younger users may be more likely to embrace social media because of technology expertise. A person brought up after the advent of the Internet and digital technology is considered a *digital native*, while *digital immigrants* have had to learn these skills as adults.

Pew research also indicates differences in social media engagement for other demographic characteristics. People with higher education levels are more likely to report using social media regularly, although variation across user income levels is small. Women are more active users of social media applications compared to men, except for YouTube (with 75% men and 72% women active participants). Platform usage also seems to vary by race, with Facebook most popular among Hispanic users, Instagram used more often by Black users, and Pinterest, by White users (Pew, 2018).

Types of Social Media Applications

Technology developments, coupled with social media's worldwide popularity, has generated an expanding number of applications. Many alternatives are available in content (from news releases to personal blogs), format (text-based transmissions, sound, image, and video), and audience (individuals to groups to organizations). Although social media platforms share many characteristics, they operate in different ways; e.g., the media richness of a virtual game world versus the self-disclosure level of a Facebook post (Kaplan and Haenlein, 2010, p. 62). Joining a social media platform means the user agrees to the platform's terms, giving the site permission to use posted content and allow others to share it. Because individual dialogues rely on original content, such as posting one's own ideas or pictures, they generally circumvent copyright issues. Most platforms typically offer users some control over their activity through privacy and application settings—although some degree of self-disclosure is almost inevitable (Joose and Brydges, 2018). Indeed, the only way to maintain full control over one's personal information on social media is not to share it at all.

Among the earliest social media applications were personal weblogs (*blogs*). Blogs are online publications with brief entries in a narrative style, organized in reverse chronological order, that enable interactive comments. Some blogs are targeted to a small group of like-minded individuals; others have expanded through both social and mass media. An illustration is the "Going Zero Waste" blog (www.goingzerowaste.com) that has been featured by *National Geographic*, *National Public Radio*, *CNN*, *The Guardian*, *CBS*, and *US News and World Report*. Joosse and Brydges (2018) comment that blogs broaden the sources and platforms for environmental communication, making way for new voices—and nonexperts—on the topic. In recent years, many organizations have also become active users of corporate blogs (Fieseler et al., 2010).

Global interconnectivity allowed for the development of social networking. Early social networking sites such as MySpace were developed in the late 1990s, and were followed in 2004 by the establishment of Facebook. Facebook is the most widely-used social media platform in the world. It provides an extensive social networking capacity, also serving its users as a search directory for friends and contacts. The second most popular application is YouTube, which shares videos and music and allows users to upload original content. Other platforms, including Twitter, rely primarily on text, web links, or memes. In general, a social media update is called a *post*, except for Twitter, which calls its short posts *tweets* (up to 280 characters of text). A *meme* is an image plus short text, often meant to be humorous, that is shared on the Internet; an illustration is included in Fig. 2.

Instagram is an image-sharing platform that is very popular for personal activities; it also encourages user interaction through informal questions, quizzes, and polls (e.g., ‘What is your favorite way to recycle?’). The *Pinterest* social network allows participants to visually share interests through posts, primarily images (called *pins*, after a bulletin board). *LinkedIn* is a social networking and search platform focused on professional topics and job opportunities that also includes articles and career-related content. The *WhatsApp* application concentrates on text messaging and voice calls. Several platforms (e.g., Twitter, Instagram, and Facebook) use the *hashtag* concept (# followed by a word or phrase) to organize content, making it easier to access related documentation (Saxton et al., 2019). One illustration is *#sustainability* on Instagram, which had 3.2 million posts in early 2019. Table 1 provides a summary of the seven largest social media applications worldwide. In addition, other popular social media platforms and messaging tools (especially for younger users) include Snapchat, Skype, Tumblr, Reddit and Flickr.

Social Media in Organizations and Communities

Public and Government Organizations

The benefits of global reach, rapid transmission, and low cost encouraged social media communication to extend beyond individual networking to include organizations. Public entities, nonprofits, and governmental agencies (from local to intergovernmental) use social media actively to connect with a wide range of stakeholders. Social media offers high information access and different types of data as well as more interactivity (Joose and Brydges, 2018). Public communication may serve to transmit information (e.g., educating citizens about changes in regulations), and it also provides the opportunity to strengthen stakeholder engagement. For example, social media platforms are an integral part of many public emergency management plans, such as hurricane tracking.

Prior research has reported that civic engagement and political activism are linked with social media use, because it enables direct action as well as knowledge sharing. When citizens gain a voice through social media, industry and government lose their dominance over information (Joose and Brydges, 2018; Saxton et al., 2019). In addition, social media creates social networks that offer opportunities to participate in civic and political actions. Boulianne (2015) found the relationship between social media use and civic/political participation appeared to be positive and correlational.

Business Organizations

Corporate firms, both publicly and privately-owned, are heavy users of social media. Businesses use social media for a variety of purposes (Reilly and Hynan, 2014), such as sharing company information (e.g., on a Facebook page), responding to customer questions (perhaps through Twitter), and recruiting new employees (via LinkedIn). Many large companies maintain multiple

Table 1 Overview of key social media applications.

Social media site	Logo	Established	Primary function	Active users in 2018	Owned by	Users, age 18–29 (%) ^a	Users, college grads (%) ^a
Facebook		2004	Social networking	2.32 billion	Public: NASDAQ	81	77
Twitter		2006	Micro blog	330 million	Public: NYSE	40	32
Instagram		2010	Photo sharing	1.0 billion	Facebook	64	42
YouTube		2005	Video sharing	1.8 billion	Google	91	85
Pinterest		2010	Visually share interests	250 million	Public: NYSE	34	40
LinkedIn		2013	Professional social networking	260 million	Microsoft	29	50
WhatsApp		2009	Text messages and phone calls	1.3 billion	Facebook	27	29

Data sources: Pew Research Center; Statista; company websites.

^aPercentage of American adults as active users (Pew, 2018).

accounts: a parent company presence plus social media sites for their major brands (which may be more active than the parent company account; see Reilly and Larya, 2018), and perhaps other accounts addressing particular topics (Saxton et al., 2019). To illustrate, in 2019 General Motors maintained multiple platforms for each of its automobile brands (e.g., Buick, Cadillac, Chevrolet), a Twitter account addressing diversity (@GM_Diversity), as well as separate Twitter, Facebook, and Instagram accounts for the GM parent company and its Chair and CEO Mary Barra.

Business organizations also engage frequently with the LinkedIn platform. This application emphasizes professional networking and career development, and many firms dedicate resources to LinkedIn as an important part of their job recruitment strategy. LinkedIn also provides a useful search function that targets not only by individuals' names, but also by desired job-related attributes or demographics. This platform claimed 630 million members worldwide in 2019 (www.facebook.com/LinkedIn/).

One of the most important reasons companies use social media is to market their products and services (Reilly and Larya, 2018). As Kaplan and Haenlein (2010) comment, social media allows firms to engage in timely and direct consumer contact efficiently at low cost, and organizations frequently use multiple social media platforms to relay similar marketing content. Making sure the company's message is consistent across all media and outlets is the concept behind integrated marketing communication. Firms also gather data from consumer/company social media interaction that contribute to marketing strategies. Prior research has thus called for social media to be integrated fully within an organization's overall corporate communication strategy (Saxton et al., 2019; Herzig and Schaltegger, 2011).

Savvy organizations also look to social media *influencers* in crafting their communication plans. An influencer has a strong social media presence and established credibility, and his large audience and reputation allow him to influence other users. High-profile influencers impact others not only through direct follower engagement, but also via comments, discussions, *likes* and *shares* by their audience (e.g., *retweets* and *pins*). The sustainability realm offers multiple examples of high-impact social media influencers—including many who are high-profile because of their other roles. Film celebrity and environmentalist Leonardo DiCaprio is an illustration; in May 2019, his Twitter presence included 19 million followers. Another high-impact sustainability influencer is former Microsoft CEO Bill Gates, with 47.2 million Twitter followers in 2019. A sample tweet from his Twitter account is below:

Bill Gates@BillGates 28 March 2019

To prevent the worst effects of climate change, we need to reach near-zero emissions on all the things that drive it—agriculture, electricity, manufacturing, transportation, and buildings—by investing in innovation across all sectors while deploying low cost renewables.

In addition to message content, the freshness of corporate social media communication must be considered. Outdated information and broken links are common, and more serious problems may arise with negative content. Given the broad scope and instantaneous transmission possible with social media, organizations must be vigilant in monitoring for potential information distortion, rumors, and unofficial or unverified sources (Kaplan and Haenlein, 2010; Reilly and Hynan, 2014).

Virtual Groups and Communities

Social media has encouraged virtual groups and communities to form through its online social interaction. Like-minded users may form a public (anyone may join) or private (requires permission) group or community based on shared demographics, backgrounds, or interests: e.g., local neighbors, university alumni, or recycling advocates. Indeed, potential group members may receive an invitation to join a group, based on their network connections and platform activity. These virtual communities vary in complexity and format, and their cohesiveness generally depends on having engaged members plus an organized curator monitoring information flow and the network of connections. One popular example is a Facebook group. These groups provide information sharing and add the social networking dimension of connecting via Facebook profiles. An illustration of a public Facebook group is called 'Sustainability.' This community had over 2000 members in early 2019, and its profile notes,

About This Group: A forum for discussing important sustainability topics and sharing useful or interesting information on the subject. Looking for provocative and even controversial discussions on topics like climate change, water/food shortages, waste and pollution, biodiversity, war and many others.

Other examples of virtual communities include the blogosphere, chat rooms, and virtual worlds. The *blogosphere* generally refers to the collective online network of personal and organizational blogs (Fieseler et al., 2010). A *chat room* operates like synchronous conferencing: group members exchange text information with others in real time. Many social media users participate in *virtual worlds*, in which individuals adopt an *avatar* identity (a figure representing a person) in a fictional computer-based setting—often as part of a game (Kaplan and Haenlein, 2010). For example, *Farmville* (developed by Zynga) lets participants virtually engage in farming by planting and harvesting crops, milking cows, and collecting eggs (www.zynga.com/games/farmville).

Social Media Communication and Sustainability

Individuals and organizations use social media to communicate and interact about an array of topics, including sustainability. Sustainability is a broad construct covering a wide range of issues, ranging from individual recycling behavior to organizational

pollution monitoring to global climate change. Sustainability challenges for organizations are many, and social media applications offer the opportunity to discuss, network, and initiate action about these important issues.

An Overview of the Sustainability Construct

There are multiple approaches to sustainability; the definition used here describes sustainability as development that meets present needs without compromising the ability of future generations to meet their needs (Godemann and Michelsen, 2011). Sustainability considers responsible economic development and social objectives that preserve natural and human resources. A variety of factors underpin the growing engagement with this topic. Examples include shortages of nonrenewable resources (e.g., the rare earth minerals needed for manufacturing computers); regulatory constraints such as carbon emissions standards; consumer demand for organic and fair trade products; and community concern with the future of the planet. Given its broad scope, sustainability is often measured with multiple metrics that use the concept of *net impact*. Net impact refers to the overall impact of a sustainability action or policy when all major aspects are considered. An illustration is the trade-off in tourism development between positive employment growth and negative overcrowding in the local community.

One popular framework for assessing sustainability performance is the *triple bottom line*. This model includes environmental, economic, and social elements (sometimes called the planet, profit, and people dimensions). Fig. 1 presents an overview of this approach to sustainability, with examples of metrics. A similar model is the ESG framework that assesses Environmental, Social, and Governance measures; governance refers to an organization's leadership, controls over issues such as executive pay and audits, and shareholder rights. This framework evolved in capital markets to assess socially responsible funds, an increasingly popular investment option. Global sustainable investment assets under ESG guidelines were \$30.7 trillion in early 2018, up 34% from 2016, according to the nonprofit US SIF (the Forum for Sustainable and Responsible Investment); see www.ussif.org.

A different approach to modeling sustainability uses the *circular economy* framework. Here, the emphasis is on proactively designing a business operation to focus on restoration and regeneration. The circular model moves beyond the linear approach of making, consuming, and discarding products, focusing on three underlying principles: designing out waste and pollution; keeping products and materials in use; and regenerating natural systems. For example, circular economy techniques in a production plant may include new ways of extracting recyclable materials and remanufacturing outputs from these elements (rather than discarding). The circular economy framework is especially relevant for manufacturing firms, as the tweet below from Unilever illustrates.

Environmental sustainability

Factors affecting the physical and natural environment (air, water, land, ecosystems); being 'green'

Metrics include:

- global warming emissions, such as greenhouse gases
- other pollution
- water usage
- hazardous waste
- engagement in recycling

Economic sustainability

Activities concerning the contribution to the ongoing viability of a broader economic system

Metrics include:

- distribution of wealth
- use equitable business practices
- impact on the local economy
- flow of capital among stakeholders
- infrastructure investment.

Social sustainability

Assesses impact on the people and local area in which an organization operates*

Metrics include:

- support human rights
- foster diversity
- provide safe working conditions
- equal opportunity and fair trade
- community development
- produce safe products

*Corporate philanthropy is sometimes coupled with social sustainability

Fig. 1 The sustainability triple bottom line.

Unilever @Unilever. 9 November 2018.

We are working hard to tackle plastic packaging waste in our own operations and beyond, to help us achieve our 2025 sustainable packaging targets. We've just taken another major step forward with three new partnership initiatives #CircularEconomy.

Challenges in Measuring Sustainability Performance

Evaluating sustainability performance is complex, not only due to multiple metrics. As yet, few agencies require monitoring of sustainability measures, and independent third-party assurance (comparable to accounting audits) is not yet in general use. Although European Union rules mandate regular reports (from 2018) on the social and environmental impacts of large company activities (see www.ec.europa.eu/info/business-economy-euro_en), sustainability information is often self-reported data published on a voluntary basis. Some firms do participate in the Global Reporting Initiative (GRI), an independent, international organization established in 1997 that seeks to make sustainability reporting a standard practice (www.globalreporting.org). In addition, some industries do employ self-regulation (Herzig and Schaltegger, 2011). One example is Leadership in Energy and Environmental Design (LEED) certification (Platinum, Gold, Silver, and Certified) awarded for green building construction worldwide (<http://leed.usgbc.org>).

A related issue is the sophisticated nature of many sustainability metrics (Reilly and Hynan, 2014). These may require translation of technical terms not familiar to the community at large: carbon offset trading, the Human Development Index (HDI), and gray water are examples. This challenge is especially relevant in social media, where messaging is brief and often visual. Technical experts in sustainability are needed to translate their expertise to the nonexperts—corporate leaders, politicians, and consumers—who will be making sustainability policy decisions. Further, lack of standardized metrics makes it difficult to compare sustainability performance across industries and organizations (Herzig and Schaltegger, 2011; Reilly and Hynan, 2014). Without required and standardized metrics, many organizations are able to focus their sustainability communication on areas in which they perform well or receive awards. The following is an example from Nestlé's corporate website (www.nestle.com):

We are not driven by awards and recognition. Nonetheless, we are proud to have our sustainability efforts and achievements acknowledged in 2018 by world-leading ratings and rankings agencies. We are also open to working with their suggestions to support continuous improvement.

Greenwashing

With the prevalence of self-reported data, sustainability social media communication is especially prone to *greenwashing*: misrepresenting actual sustainability practices or activities to promote a false image of responsibility (Saxton et al., 2019). Prior research has noted that organizations are reluctant to disclose sustainability 'bad news,' leading to overly positive messaging (Reilly and Hynan, 2014). According to Herzig and Schaltegger, communication about sustainability is often characterized by information asymmetry in which the audience cannot easily access firm sustainability data, leading to low credibility (2011, p. 157). Thus, organizations may be able to portray themselves as sustainability stewards because stakeholders must rely on the companies' own messaging. One greenwashing illustration is Procter and Gamble's announcement of its 2018 introduction of Pampers Pure Diapers:

For parents searching for diaper and wipe options in the "natural" category who don't want to sacrifice performance, the new Pampers Pure Collection offers another choice. It is the first-ever diaper and wipe collection made with premium cotton and other thoughtfully selected materials, stylish prints, and the Pampers protection.

(See Procter and Gamble News Releases: https://news.pg.com/news_releases/all/all/all Thursday, February 22, 2018 11:34 am EST).

Calling disposable diapers and wipes 'pure' and 'natural' ignores that these products require energy to produce, are not recyclable and generally end up in landfills.

Sustainability and Social Media at Multiple Levels

Individual Sustainability and Social Media

The interactive and inexpensive characteristics of social media have contributed to its popularity among individuals engaged in the sustainability domain. Several studies have examined bloggers who actively post about personal choices that support sustainability, such as Joosse and Brydges' (2018) study of green bloggers. According to Joosse and Brydges, these bloggers serve as ordinary nonexperts acting as intermediaries of information about topics including a sustainable lifestyle, beauty products, and food (2018, p. 689). Such sustainability communication may support a process of individual and voluntary behavioral change, such as water conservation or recycling (Godemann and Michelsen, 2011). In addition to tracking their own personal sustainability achievements, many individuals blog about the sustainability progress (or lack thereof) by business and public organizations.

Business Organization Sustainability and Social Media

Business firms regularly use multiple social media platforms to communicate about sustainability (Reilly and Hynan, 2014). As Saxton and his colleagues note (2019), simply creating a related social media account suggests a company is signaling its engagement in the sustainability agenda. Sustainability reporting indicates an organization's willingness to communicate about societal issues, contributing to a positive relationship with its stakeholders (Herzig and Schaltegger, 2011). Stakeholders have become increasingly aware—and often critical—of corporate sustainability performance (Fieseler et al., 2010), so sharing their sustainability activities has become an integral component of many firms' corporate communication (Reilly and Larya, 2018). Below is a Twitter example from McDonalds:

McDonalds Corporation @McDonalds Corp. 9 May 2019.

DYK [Did you know] that we'll be using packaging made from renewable, recycled or certified sources by 2025. So far, we've eliminated more than 300 million pounds of packaging, recycled 1 million tons of corrugated boxes and reduced waste by 30%.

<http://McD.to/6011E9k95> #ScaleForGood.

Some prior research has indicated that a company's sustainability engagement may follow multiple paths. Many initiatives are directed by top management strategy, such as a firm-wide program to reduce solid waste production in manufacturing. But other activities may be grass-roots changes driven by lower-level employees; e.g., an in-house recycling program (Reilly and Hynan, 2014). Herzig and Schaltegger (2011) propose that corporate sustainability communication should consider internal stakeholders (employees and managers) as well as external constituencies (consumers, stockholders, and the media). Whether the messaging is vertical or horizontal and internal or external, social media offers a critical tool for effective sustainability engagement and dialogue (Fieseler et al., 2010). Fig. 2 provides some illustrations of sustainability-related social media messaging.

Public Organization Sustainability and Social Media

The broad sustainability agenda is also relevant for policy makers in public organizations. Indeed, the missions of many public agencies deal directly with sustainability issues, ranging from environmental preservation (e.g., the European Environment Agency) to health (the U.S. Department of Health and Human Services) to workplace conditions (United Nations International Labour Organization). These organizations also have multiple stakeholders—citizens, employees, activists, and the community at large—that hold them accountable for their sustainability performance. Boulianne (2015) found that civic and political engagement correlated positively with social media use, and social media content from companies perceived as socially responsible is more likely to be shared (Saxton et al., 2019, p. 374). Further, the interactive nature of social media allows for an immediate response, which is helpful in implementing sustainability programs or calling for action.

Given the broad reach of international public organizations, they are often expected to provide sustainability leadership because issues such as climate change, water shortages, and social inequity cross national borders. One example is the United Nations' 17 Sustainable Development Goals, adopted by all UN Member States in 2015 as part of the 2030 Agenda for Sustainable Development. The 17 goals seek to provide a shared blueprint and a call for action at the global level, and they address a wide array of environmental, economic, and social sustainability challenges (<https://sustainabledevelopment.un.org/sdgs>). A list of the 17 UN goals is presented in Fig. 3.

Community Sustainability and Social Media

Social media sustainability communication may diverge across various forms of communities. Godemann and Michelsen (2011, p. 6) propose that the task of sustainability communication is to introduce an understanding of the relationship between people and their environment into broader social discourse. Different communities will have diverse interpretations about these elements—and the nature of social discourse itself. Boulianne (2015) points out that social media provides a forum for information and news that is often filtered through a network of trusted others. These networks—and the trusted others in them—will vary, leading to corresponding differences in messaging. Demographics continue to matter: Table 2 shows that platform usage varies by community type, with rural users least active across platforms, perhaps reflecting Internet availability.

Community social media activity may also reflect differences in purpose and location. While some sustainability challenges (e.g., climate change) are global, others may relate specifically to particular users. For example, high-profile sustainability challenges in urban areas may include employment disparity and unequal access to public education, while sustainability concerns in rural and agricultural districts may involve genetically-modified crops and animal welfare. Social media is frequently used to support non-profit activist and social movement actors (Saxton et al., 2019), such as #girlrising, a global movement to educate girls that had 117,000 followers in early 2019. In addition, sustainability messaging also reflects characteristics of the communities involved. The tweets below contrast environmental sustainability posts for a rural wilderness area (Grand Teton National Park in Wyoming) with that of the Sierra Club in urban Chicago.

Sierra Club Chicago @SierraChicago 10 May 2019.

We're very grateful to the musicians of the Civic Orchestra of Chicago for putting together this string quartet program celebrating nature, on Sunday, May 19. Enjoy an afternoon of beautiful music, and help plant seeds in a community garden!

Conclusions

Social media has revolutionized global communication in many realms, including sustainability. Researchers and users alike agree that social media messaging and format will continue to shift, tracking developments in technology. New applications are introduced regularly, often extending current platforms' functionality and user appeal. Social media market penetration is expected to grow, although some countries do monitor or censor online information access and interaction (including China, Iran, and North Korea). While digital sustainability messaging offers many benefits, important challenges remain.

One critical ongoing problem affecting social media communication is source credibility. Limited government monitoring, much self-reported data, and stale information contribute to this problem. Sharing information via social media is simple and (if desired) anonymous, permitting easy transmission of 'fake news.' According to Jooisse and Brydges (2018), social media sources are often viewed as providing low-quality information, frequently serving as 'echo chambers' to confirm already-established opinions. In addition, the tremendous amount of social media information available may lead to information overload (Herzig and Schaltegger, 2011). Kaplan and Haenlein (2010) point out that the growing number of outlets and platforms, coupled with the high volume of messages, make it difficult to analyze social media activity—in any realm—in depth.

Social media users thus may benefit from a healthy skepticism in interpreting messaging. Consider the source: Is the data provided by an organization with stringent ethical reporting guidelines, such as a reputable news organization, an established educational institution, or a respected research agency? Independent fact-checking websites exist, such as FactCheck.org, a project of the Annenberg Public Policy Center of the University of Pennsylvania (www.factcheck.org). Furthermore, reports released on social media may be funded by organizations with ideological agendas, or sponsored by entities with a direct interest in the outcomes. A well-known example is the tobacco industry. Despite the 1964 U.S. Surgeon General's report outlining the health dangers of nicotine, tobacco companies continue to market cigarettes today.

Another fundamental concern is the right to individual privacy for documentation collected and shared over the Internet. High-profile lawsuits involving Facebook and other companies illustrate that social network platforms may track, save, and reveal private information such as personal identification and online browsing histories. According to a Pew survey, about 80% of American social media users reported anxiety about advertisers and businesses accessing data shared on social media platforms; almost two-thirds called for more government regulation (Pew, 2018). While public safety issues are clearly important (such as monitoring threats posted on social media), so also is the privacy of personal information.

Within the sustainability domain, resource scarcity and climate change suggest that global interest in sustainability will continue, supported in part by social media communication. Some intriguing questions here concern underlying values. For example, where does responsibility for sustainability rest—with personal, organizational, or government actions? (see Joosse and Brydges, 2018) Individual decisions contribute to sustainable lifestyle choices, but broader environmental, economic, and social issues arguably demand broader responses. Sustainability policy decisions may also challenge long-held beliefs about individual and organizational behavior. To illustrate, Joosse and Brydges (2018) noted differences in how individual consumption and sustainability preferences varied about 'needing versus wanting' goods. Sustainability choices may also relate to the field of macromarketing, which addresses how society as a whole distributes goods and impacts consumer behavior via marketing strategies. Decisions such as these, coupled with emerging technologies, suggest that social media will continue to impact sustainability actions for the future.

Abstract

This article is divided into three sections. The first deals with the ways in which ideas of anthropogenic biomes (anthromes) have appeared in mass media coverage of climate change and global warming. The second section addresses the ways in which ideas of anthromes have appeared in mass media coverage of the Anthropocene. While the precise specifications of anthropogenic biomes have varied somewhat over time, our focus is on the six main categories, namely dense settlements/urban, croplands, rangelands, forests, wildlands, and indoor anthromes. In the third section, we draw out some conclusions from these findings.

Introduction

There are many reasons why it is important to study how scientific concepts are introduced to the public via the mass media. Often this can be a vital process of translating the complexities and nuances of jargon-laden science reports into language that the lay reader can understand. Drew Westen and Celinda Lake have written, “we tend to speak to [citizens] in our language—the language of parts per million, carbon emissions, carbon sequestration, and the like—and expect [the public] to make the translation. We would do well to make that translation ourselves...” (2009). These challenges can be partly attributed to long-standing differences between the ‘Two Cultures’ first explained by CP Snow in the 1950s.

From the invention of the Gutenberg printing press in 1450 and expanded opportunities for communication on a larger scale, books, and pamphlets, ideas, arguments, stories and commentaries began to circulate throughout various segments of society. These seeds of ‘media’ sprouted all over the world in the decades that followed, leading to a growing role in translating (information, concepts, developments, debates) from formal and often insular spaces of scientific research into communities and the public sphere.

Nonetheless, there have been many ongoing challenges of translation. Within language resides the power to effectively (mis) communicate. Differences in language use between science, policy, media and civil society can unavoidably impede efforts to make climate change, the Anthropocene—or any other issue—meaningful in society. Frankly, important research, effective arguments, and interesting insights from science often suffocates under a wet blanket of jargon and complexity. Clinging to nuance has led to alienation of the decision-makers and audiences that the research often seeks to influence in the first place. It is a struggle to translate complicated science into crisp and resonant commentary that is valued in policy communities and in civil society. Yet this is not necessarily a process of ‘dumbing down’ science for public understanding and engagement but can result in ‘smartening up’ communication of the science in order to effectively meet people where they are in the Anthropocene. In reality, scientific findings usually require translation into more colloquial terms in order to be comprehensible and valued in decision-making from the individual to the collective scales. One example of this is anthropogenic biomes or anthromes (defined below). The media, in all its manifestations, has become the main conduit between science and the general public.

The ways that the Anthropocene and anthromes are discussed in the public arena matter. Among many examples, renowned UK science and environmental filmmaker David Attenborough has credited Ralph Cicerone—then president of the US National Academy of Sciences—for delivering a rousing talk in Belgium in 2004. That public talk managed to convince the influential Attenborough of the case for the importance of anthropogenic climate change (Randerson, 2007).

In the public arena, communications through mass media provide a bridge between the formal spaces of science-policy interactions and our everyday lives. In reality, few people spend part of their typical day perusing the latest peer-reviewed research. Instead, citizens more regularly turn to mass media. Mass media play important roles in people's everyday realities and experiences and the ways in which these are discussed at a distance between science, policy and public actors. People throughout civil society rely upon media representations to help interpret and make sense of the many complexities relating to science, governance and society. Furthermore, media messages are critical inputs to what becomes public discourse on today's issues, problems and challenges.

While the precise specifications of anthropogenic biomes, or anthromes, have varied somewhat over time, our focus is on how the main categories, namely dense settlements (urban), croplands, rangelands, and forests (See Ellis and Ramankutty, (2008). On indoor anthromes, a recent addition, see Martin et al., 2015), are represented in the media. In his popular introduction to the Anthropocene, Ellis expands on the original specification of anthromes as follows: 'anthrome landscapes are generally mosaics of used lands interspersed with less used, recovering, and remnant ecosystems transformed by being broken up and embedded within used landscapes' (2018: 121).

Anthromes in the Climate Change Mass Media

To appraise the presence of the terms climate change, and 'Anthro' (The Boolean we used was 'climate change OR global warming AND anthro'. This approach allowed for the appearance of combinations from the root 'anthro' including Anthropocene, anthromes, anthropogenic and so on. We used the Nexis Uni, Factiva and Proquest databases in order to determine these counts. Secondary checks were also made to validate the returns.) in the media, researchers at the University of Colorado monitored coverage in 12 United Kingdom (UK) and United States (US) newspapers from January 2009 through December 2018. These sources are the *Daily Mail & Mail on Sunday*, *Guardian & Observer*, *The Sun*, *News of the World & Sunday Sun*, the *Telegraph & Sunday Telegraph*, the *Daily Mirror & Sunday Mirror*, the *Scotsman & Scotland on Sunday*, and the *Times & Sunday Times* in the UK (Fig. 1) along with the *Washington Post*, *Wall Street Journal*, *New York Times*, *USA Today*, and *Los Angeles Times* in the US (Fig. 2).

We found that in the US media, coverage steadily increased over this 10-year period. In the first 5 years (2009–13) coverage of climate change and anthro-appeared 123 times, while coverage in the following 5 years (2014–18) was evident 332 times. Of the five sources monitored, the *New York Times* had the most coverage of climate change or global warming and anthro-overall ($N = 319$) followed by the *Washington Post* ($N = 119$). Comparatively, there was scant attention paid to climate change or global warming and anthro-in the *Wall Street Journal* ($N = 2$), *USA Today* ($N = 8$) and the *Los Angeles Times* ($N = 7$) over these 10 years,

This figure tracks newspaper coverage of climate change or global warming and 'anthro' in 5 US newspapers (Washington Post, Wall Street Journal, New York Times, USA Today, and Los Angeles Times), month-to-month from January 2009 - December 2018.

Fig. 1 This figure tracks newspaper coverage of climate change or global warming and 'anthro' in five US newspapers (Washington Post, Wall Street Journal, New York Times, USA Today, and Los Angeles Times), month-to-month from January 2009–December 2018.

This figure tracks newspaper coverage of climate change or global warming and 'anthro' in 7 UK newspapers (Daily Mail & Mail on Sunday; Guardian & Observer; Sun, The News of the World & Sunday Sun; Telegraph & Sunday Telegraph; The Daily Mirror & Sunday Mirror; The Scotsman & Scotland on Sunday; and Times & Sunday Times), month-to-month from January 2009 - December 2018.

Fig. 2 This figure tracks newspaper coverage of climate change or global warming and 'anthro' in seven UK newspapers (Daily Mail & Mail on Sunday; Guardian & Observer; Sun, The News of the World & Sunday Sun; Telegraph & Sunday Telegraph; The Daily Mirror & Sunday Mirror; The Scotsman & Scotland on Sunday; and Times & Sunday Times), month-to-month from January 2009–December 2018.

averaging less than a story a year. Together, the *New York Times* covered climate change or global warming and anthro-more than the other four sources combined over this 10-year period, pointing to possible differences in editorial directives, ownership structures, and story allocations (Boykoff, 2011).

In the UK media, we also found overall increases across this 10-year period. We found that there were 348 stories in the first 5 years (2009–13) that explicitly addressed climate change and anthro-, while 505 stories in the following 5 years (2014–18) included those terms. Of the six UK sources that we studied, the *Guardian/Observer* contained the most coverage of climate change or global warming and anthro-overall ($N = 587$) followed by the *Times and Sunday Times* ($N = 123$). In contrast, the *Daily Mail* ($N = 14$) and the *Daily Mirror* ($N = 1$) largely ignored stories of climate change or global warming and anthro-over this 10-years period. These numbers by media outlet show stark differences that could be linked to newsroom practices and editorial agendas within the newsrooms and ownership as *The Guardian* alone provided more coverage than the other five news organizations combined (Boykoff, 2011).

US and UK coverage combined has shown that coverage including climate change or global warming and anthro- overall has increased over the 10-year period with 183 total stories in 2018 compared to the following high amounts of coverage in 2016 ($N = 177$), 2015 ($N = 171$), and 2017 ($N = 164$). However, while coverage of the US also followed this general pattern of higher coverage in recent years (e.g. the most abundant coverage in 2016–18), coverage in the UK specifically peaked in 2015 ($N = 122$) and 2016 ($N = 115$) when coverage of the Paris climate accord pervaded public discourse. Combined, there were 471 stories on climate change or global warming and anthro-in the first 5 years of study (2009–13) (on average 24.6 per year in the US and 69.6 in the UK) and 837 stories in the second five-year window (2014–18) (on average 66.4 per year in the US and 101 in the UK). These findings also point to more abundant coverage in the UK press ($N = 853$) than the US press ($N = 455$) over this 10-year period overall, even when normalizing for stories per source in each country (as we tracked coverage in five US publications and six UK publications) (Fig. 3).

Evident increases can be seen in media in both the UK and US in similar periods of time. These increases are associated with scientific, ecological/meteorological, political, economic and cultural themes (Boykoff, 2011). For instance, initial increases in 2009 were associated with the United Nations climate talks in Copenhagen, Denmark (COP15), along with news about the hacked emails of scientists from the University of East Anglia (UEA) Climate Research Unit (CRU) in the preceding week, (not so affectionately referred to by many on the ideological right as 'Climategate'). The initial release of the 'Planetary Boundaries' research in the journal of *Ecology & Society* also generated media discussion of these links between climate change or global warming and the

Fig. 3 This figure tracks newspaper coverage of climate change or global warming and ‘anthro’ in US newspapers (*Washington Post*, *Wall Street Journal*, *New York Times*, *USA Today*, and *Los Angeles Times*), UK newspapers (*Daily Mail & Mail on Sunday*; *Guardian & Observer*; *Sun*, *The News of the World & Sunday Sun*; *Telegraph & Sunday Telegraph*; *The Daily Mirror & Sunday Mirror*; *The Scotsman & Scotland on Sunday*; and *Times & Sunday Times*) and all 12 sources together, month-to-month from January 2009–December 2018.

Anthropocene (Rockström et al., 2009). Increases in 2015 and 2016 can be attributed to attention surrounding the Paris round of United Nations climate talks and the resulting Paris Agreement (Boykoff and Lueddecke, 2016).

It is useful to also compare these searches and the wider searches of climate change or global warming through the Media and Climate Change Observatory, where co-author Boykoff is lead Project Investigator. The total US counts of global warming or climate change for across the same five sources—*Washington Post*, *Wall Street Journal*, *New York Times*, *USA Today*, and *Los Angeles Times*—over the 10 year period (2009–18) is 32,006 articles. Compared to the 455 returned through the more specific ‘climate change OR global warming AND anthro’ Boolean string, these articles comprise 1.4% of that wider coverage. Similarly, UK comparisons across the six sources—*Daily Mail & Mail on Sunday*, *Guardian & Observer*, *The Sun*, *News of the World & Sunday Sun*, the *Telegraph & Sunday Telegraph*, the *Daily Mirror & Sunday Mirror*, the *Scotsman & Scotland on Sunday*, and the *Times & Sunday Times*—over the 10 year period (2009–18) returned 62,163 articles. Compared to the 853 articles generated through the more specific ‘climate change OR global warming AND anthro’ Boolean string, these articles also comprise just about 1.4% of that wider coverage. Across these 11 sources in the US and UK, 94,169 articles covered climate change or global warming from 2009 through 2018 (The Boolean used by the Media and Climate Change Observatory (MeCCO) is ‘climate change OR global warming.’ These US and UK newspaper sources comprise a subset of 96 sources (across newspapers, radio and TV) in 43 countries in seven different regions around the world that we monitor monthly through Nexis Uni, Factiva and Proquest databases. Each count is checked by a second counter in order to improve the validity and reliability of our monitoring. This involves a team of eighteen researchers around the world, based primarily at the University of Colorado but also at the National Institute for Environmental Studies (Japan), University of New England (USA), Universidad de Sevilla (Spain), Universidad Complutense de Madrid (Spain), Babson College (USA), and Oslo Metropolitan University (Norway)). Therefore, even though the raw counts in sources in the US and UK have varied over time (see Appendix), the percent coverage across these two countries over this 10 year period (2009–18) is approximately the same (1.4%).

Anthromes in the Anthropocene Mass Media

Interest in the Anthropocene as a potentially new geological epoch has increased rapidly since the term entered the public realm around the start of the new millennium. Though not achieving the volume of coverage of climate change and global warming in the mass media (which began in the 1980s), by the second decade of the 21st century if you were regularly browsing newspapers, magazines, or online sources in many countries in the world for the daily news you might come across mentions of the Anthropocene once or twice a year, more often if you were reading the quality press. However, in a study of coverage of the Anthropocene in the mass media (see Sklair, 2009 ed. forthcoming, hereafter referenced as AMP) (The websites of around 2,000 newspapers, magazines and online news sites were manually searched, finding over 4,000 items that mentioned the term ‘Anthropocene’.), very few items made direct references to anthromes.

The first mass media reference to anthromes found in an item that also mentioned the Anthropocene was by Brandon Keim in the magazine *Wired* (August 27, 2010). 'Maps: How Mankind Remade Nature,' was based on the 2008 article by Ellis and Ramanakutty 'They called their newly-defined areas "anthromes," short for anthropological biomes. It was a map for the *anthropocene*' (Quotes from media sources (translated where necessary) have been edited for clarity. Articles can be accessed by sources and title. Translations from non-English language sources are by researchers from their mother-tongues or translation software, often embedded in media websites. This was often a frustrating task as some languages (notably Japanese) appear to have several terms for the Anthropocene.). In 2011 Andy Revkin in his influential dot.earth blog in the *New York Times*: 'Confronting the Anthropocene' described a presentation by ecologist Erle Ellis 'a mesmerizing tour of the planet's profoundly humanized systems, which he said would be better described as "anthromes" than "biomes."' Ellis said it was important to approach this reality not as a woeful situation, but an opportunity to foster a new appreciation of the lack of separation of people and their planet and a bright prospect for enriching that relationship.' Revkin revisited anthromes several times in subsequent articles in the *Times* and elsewhere (For the influence of Revkin in publicising the idea of the 'good' Anthropocene, see Sklair, 2009 ed. (forthcoming, chapter 4)). In 2015 the *Independent* newspaper (UK) reported: 'The idea of a domesticated Amazonia, the immense diversity of social, cultural and historical processes that shaped Amazonia during the Holocene, situates this vast area in the company of other world anthromes.' The online magazine *The Conversation* (2016) published 'Humans now drive evolution on Earth, both creating and destroying species,' by the prominent Anthropocene researcher Mark Maslin who cites the work of Ellis on Anthromes. Maslin discusses both loss of biodiversity and emergence of new species (for example, the common house mosquito (*Culex pipiens*) which has become 'adapted to London's underground railway,' an unusual shared anthrome. Also in 2016 the Chinese newspaper, *Jing Bao* (Shenzhen) under the heading 'The Beauty of Nature in the Human Age,' reviews Diane Ackerman's popular science book, *The Human Age* in 'Is nature "natural" anymore?,' explaining Ellis's term anthrome as 'global ecological patterns created by sustained direct human interactions with ecosystems.' And in a rare example from the creative arts, in 2018 *Boulder Weekly* reported on an exhibition 'Anthrome' by Jason DeMarte: 'the artist chose a word he came across that means hybrid human-natural systems that now dominate the Earth's surface... It means that in the future everything natural will have some sort of human element in it'. The Anthropocene Media project research turned up more than 600 arts references to the Anthropocene (Sklair, 2009 ed. forthcoming, chapter 13). Despite this paucity of direct references, the idea of anthromes (without citing the term itself), appears very regularly in mass media coverage of the changes in the Earth System that have led to the Anthropocene. Let us now turn to a small selection of articles from a much larger archive on the six major categories of anthromes. This may serve readers as a bridge from everyday experiences of city life, pollution, deforestation, fire, floods and drought, to the idea of the Earth System.

Dense Settlements/Cities/Urban

Anthropocene coverage in the mass media often highlights the connection between urban settlements and anthropogenic biomes. In the Czech mainstream weekly journal *Geoskop* (2013) we find: 'The Anthropocene is not only geologically, but also a cartographically important phenomenon (dense settlements and large infrastructures).' Similarly, *La Hora* (Chile) in 2016, 'The Earth enters a new geological epoch... In the Holocene, human societies increased food production with the development of agriculture, built urban settlements and took advantage of the planet's water, mineral and energy resources' (reprinted in *Ambito Financiero*, Argentina). *The Post* (Athens, Ohio) 'Southeast Sustainability' (2016) is more explicit: 'The Holocene's stability allowed humanity to take advantage of ecosystem services... to develop their settlements. Those settlements, however, have now proliferated... they threaten the stability that initially allowed them to come into being.' From Singapore, the *Straits Times* in 2015, 'Cities power the way into new epoch' tells a different story: 'Cities are efficient users of resources and are best placed to deal with environmental challenges. For Singapore, this brings opportunities... Singapore thus has the opportunity to contribute to global solutions for sustainable urban growth in many areas. Indeed, Singapore was the highest ranked city in the Economist Intelligence Unit's Asian Green City Index' (According to Eco2 Index ratings Singapore was one of the worst ecological performers in the world. <https://www.int-res.com/articles/theme/m530p271.pdf>).

The *Daily Telegraph* (UK) in 2017 goes a little further in a review of *Provisional Cities: Cautionary Tales for the Anthropocene* by Renata Tyszczyk which explores cities as 'exemplary sites for thinking about living in this unsettled time.' Many sources draw attention to the ecological impacts of rapid urbanization. Examples include 'Making a difference' in *The Himalayan* (Nepal) in 2017: 'Once an ecological hot spot, Kathmandu, ten decades ago, was very different from the maze of concrete and buildings it is today. The air was not thick with dust and smoke requiring people to wear a mask; the rivers were not dirty with black slime and there was a decent amount of greenery in the valley. Smog is ever present over cities during the winter months. The drains that are directly empty on the rivers in the capital have wiped out the aquatic life in these rivers. Effects of biodiversity loss through deforestation can be seen in mere years, not in hundreds of years or even decades today. Droughts and massive flooding have increased in duration and magnitude over the past decades.' *Daily Star* (Bangladesh): 'Urbanisation signal detected in evolution' (2017) reports 'changes that were observed in more than 1,600 studies were having an impact on evolution and that human activity, in the form of urbanisation, would have a lasting legacy on life on Earth.'

Croplands

Supporting the idea of anthromes as mosaics, many media references to crops and croplands also engage with other anthromes, as the following items illustrate. *India Today* (2014) 'Ancient Maya activities left lasting impact on environment' reports that researchers

believe that the Maya used water management to adapt to climate change. In studying the wetland systems, we were surprised to find a combination of human and natural contributions (the term Mayacene is used as an early form of Anthropocene); the *Daily Express* (UK) with 'Climate change shock as professor says impact has been GOOD [sic] for wildlife' (2014) reports the research of Professor Chris Thomas who argues that nature is fighting back against human industrialization of the globe... citing the impact of the cane toad on an array of native creatures after it was introduced to Australia from south America to eat beetles on agricultural crops'; and *New Scientist* (2014) in 'Should we upgrade photosynthesis and grow supercrops?' declares: 'Crops with turbocharged photosynthesis will be growing in our fields in a few decades. But there is a danger too.' The *Daily Mail* (UK) in 2015 discussed 'the irreversible transfer of crops and species between the New and Old worlds' (the Columbian Exchange). The *Irish Examiner* (2015) 'Video: Will Humanity be Extinct in 100 Years?' is one of several items to connect water, croplands and potential extinction: 'With no alternative to water not only would millions die of thirst but the ground will be unable to provide us with crops.' Poland's *Krytyka Polityczna* (2015), quoting from an article by George Monbiot first published in the *Guardian*, puts the situation bluntly: 'Without concern for the soil, humanity will not survive. Earth owners around the world are taking part in an orgy of the destruction of the soil on a gigantic scale.' Taking this a little further, the US-based *Scientist* magazine (2016) explains simply 'Speaking of Microbiology... In the Anthropocene, we have lost millions of tons of soil fungi due to conversions of forests to cropland'; *Gazeta po Ukraiński* reported in (2016): 'Could the first farmers cancel the ice age?... The spread of agriculture about seven thousand years ago... to free land for crops and pastures, people burned the forest and, as a result, the amount of carbon dioxide and methane in the atmosphere has increased to such an extent that instead of cooling, there was a warming' (referencing the work of William Ruddiman on the 'early Anthropocene'). *Fox News* (2015) asks: 'Have Humans Caused a New Geological Era?' reporting a scientist who explains: 'when farmers clear-cut forests and plant crops, they change how sediments and runoff wash into the local rivers, often creating a thick layer of silty, sandy clay on the flood plain... But using such geologic clues to date the Anthropocene era runs into a problem: agriculture began at different times around the globe. Some areas, such as certain pockets in Africa, may not have had intensive agriculture until recently' (This connects with debates around start dates for the Anthropocene, a topic often covered in the media.)

Rangelands

In 2008 two articles from the USA discuss rangelands in the context of the Anthropocene. Science journalist Cornelia Dean addresses this as a regional issue in the *New York Times* with 'The Southwest in the Anthropocene,' where she argues, 'Until recently, natural landscapes varied as droughts came and went, warm years were followed by cold years and so on. Now, though, the actions of people have widened the parameters of this natural change, with potentially troubling results in places like the Southwest,' citing William deBuys in the magazine *Rangelands*. In *Mother Jones* 'Us to Earth: We Will Rock You': Soil scientists at Duke University say that these days, even the dirt beneath our feet is man-made, quoting lead researcher Daniel Richter: 'With more than half of all soils on Earth now being cultivated for food crops, grazed, or periodically logged for wood, how to sustain Earth's soils is becoming a major scientific and policy issue.' The popular German weekly *Welt am Sonntag* (2009) puts this issue in starker terms: 'Can we survive the "anthropocene" period?... the methane-producing cattle population has risen to 1.4 billion, contributing to the increasing rate of destruction of tropical rainforests, which releases carbon dioxide and contributes to faster species extinction. Land conversion for grazing (and construction), together with crop tillage, has also caused soil erosion at 15 times its natural rate.'

Forests

Many media articles speak of forests and deforestation. Several items in *News International* (Pakistan) engage with deforestation, for example in 2013 'A forest without trees... One of the ways to fight this menace of environmental destruction is to carry out afforestation at a massive scale and protect the existing trees. But instead of protecting trees, the country seems to be on a tree-cutting spree... Mangroves forest depleting due to man-made mess.' *Gulf News* (2014) assessing Kolbert's book *Field Notes on a Catastrophe* (published in 2006) reports on: 'the extent to which tropical forests in Peru can adapt to rapid change, of habitat fragmentation in the Amazon basin and beyond, and of the consequences of the mass global transference of species from one place to another. It is all pretty grim.' This depressing theme is reinforced in the news website *Guinea Live* in 2015, 'Ebola and Advocacy for the Environment... One of the main causes [of the crisis] is the drastic reduction in the area of forest heritage and wildlife habitat... The natural habitats of wild animals are dangerously reduced'; *Misiones* (Argentina) in 2015 with 'This type of action would reduce the problems we will have in this century to live in the Anthropocene' reports research on 'multiple ways to lessen the alarming disappearance of forests around the world, such as stricter conservation policies, better forest management, and a global framework for climate change policies. Forests are ecological superheroes: they ventilate the planet, nourish the Earth's habitats, regulate the global climate and carbon cycles. From the poles to the equator, our survival depends entirely on healthy forests... this biome is much more threatened by direct anthropogenic contact... it is very possible that humans can curb damage to forests and perhaps even reverse it in some places... it seems suicidal not to consider this option'. We find support for this conclusion in *L'Express* (Canada), 'The environment in 2017: sowing seeds of optimism' reports on the research of Professor Elena Bennett, 'targeting a more positive future with her [Seeds for a Good Anthropocene project](#)... [her] favorite example is a project named Health in Harmony where they work in Borneo, Indonesia to reconnect with forests and healthy people. People receive [health] care at little or no cost in return for the promise to protect local tropical forests and its residents, the orangutans.' *The Independent* (UK) in 2015: 'How we must adjust

our lifestyles to nature: Welcome to the Anthropocene, the human epoch' concludes with a striking anthropogenic image: 'the scrolling text on TV news should show us not only share prices, but data about the size of forests and bogs, about air quality, energy use and bird populations'. Finally, *Sanlian Life Week* (China) in 2012 connects rising populations and anthromes philosophically: '7 billion population—how dangerous is the earth?' arguing 'Glaciers, oceans, forests, once represented certain borders of the world, they were the objects on which human put their fantasy and awe. Now they are precarious under human footprint.'

Conclusion

The science of the Anthropocene and anthromes is very complicated and it is not surprising that journalists do not always report fine detail or the implications of research findings entirely correctly. The complexity is exemplified by a study by Gaffney and Steffen (2017), which mapped out an 'Anthropocene Equation' to clearly articulate human influences on climate change and our life-supporting ecosystem services. This publication was discussed in newspapers all over the world with, understandably, varying degrees of accuracy and attention to detail (for example, in *Gulf Daily*, *India Today*, Indonesia's *Femina*, Iran's *Financial Tribune*, Pakistan's *The Nation* and *Pakistan Today*, Spain's *La Voz de Galicia*, *Al Ghad* in Syria, *The Guardian*, *Star Tribune* from Minneapolis-St. Paul, and *New York Post*). Gaffney and Steffen noted that humans are changing the climate about 170 times faster than natural forces would do alone, which made an eye-catching headline. They concluded that 'the rate of change of the Earth system over the last 40–50 years is purely a function of industrialized societies. Anthropogenic sources contributing to this Anthropocene Equation—affecting the distribution of energy across the planet—include fossil fuel burning (primarily coal, gas and oil) and land use change. This has prompted considerable discussion on how to develop policies to address these developments in the Anthropocene. These processes have been referred to as dimensions of environmental politics (Löwbrand et al., 2015) and have also been dubbed 'Anthropocene Geopolitics' (Dalby, 2007; Clark, 2014).

When reporting on debates among scientists who research anthromes, climate change, and the Anthropocene, journalists are confronted with a heavy responsibility to represent findings accurately, and to draw reasonable conclusions from the evidence in ways that members of the general public (and politicians and corporate executives) will understand and that might help to change behavior to minimize potential risks. In the Anthropocene era, media are powerful and important interpreters of Earth System science and science policy, and journalists have the opportunity of translating what can often be alienating, jargon-laden information into information that all sections of the public could understand. The apparent inability of governments and owners of major industries to take decisive action to deal with what most scientists appear to believe is a series of rapidly accelerating ecological emergencies does not bode well for the future of human life on the planet. Few opinion-formers in the media communicate a sense of urgency. Despite media focus on renewable sources of energy (none of which are carbon neutral) and the need to curb population increases and consumption in richer and poorer societies, research suggests that the media generally neutralize the potential risks of the Anthropocene. This is the message that media reporting of anthromes generally sends.

Acknowledgments

Leslie Sklair thanks the volunteer researchers (about 40 in number) from all over the world who searched media in their mother tongues for articles that mentioned the Anthropocene and, in some cases, analyzed the contents of articles found. They will all be credited by name and specific contributions in the forthcoming book on the project.

Maxwell Boykoff thanks the larger Media and Climate Change Observatory (MeCCO) team from which the climate change or global warming counts have been determined. Team members include Midori Aoyagi-Usui, Andrew Benham, Patrick Chandler, Meaghan Daly, Kaori Doi, Rogelio Fernández-Reyes, Lauren Gifford, Isidro Jiménez Gómez, Jennifer Katzung, Lucy McAllister, Marisa McNatt, Ami Nacu-Schmidt, David Oonk, Jeremiah Osborne-Gowey, Olivia Pearman, Anne Hege Simonsen, and Andreas Ytterstad. Thanks in particular to Andrew Benham for his validity checks on the counts specific to this project. Maxwell Boykoff also thanks the Center for Science and Technology Policy Research, the Cooperative Institute for Research in Environmental Sciences and the University of Colorado who have supported his ongoing MeCCO research endeavors.

Abstract

Effective science communication is imperative for successful conservation efforts. Science communication can be improved through the use of personalized frames and digital media. Communicators should be aware of potential roadblocks including jargon and science literacy and should be trained in ways to avoid these problems. By being aware that they are in fact communicating science to an audience that may be different from them in several ways, science communicators can improve their messages and have a greater chance at encouraging a positive change. This article will summarize the history and challenges of science communication and examine successful methods to apply communication tactics to conservation projects.

Introduction

Science communication can be a nebulous term that means different things to different people. As such, it is important to define science communication and related terms. Science communication can be broad: “Sharing science with non-experts” (Rakedzon et al., 2017) or “communicating science to non-technical publics” (Sharon and Baram-Tsabari, 2014). Other researchers and communicators prefer to take a more specific view. Burns et al. (2003) suggested science communication be analyzed and practiced in depth, defining it as “the use of appropriate skills, media, activities, and dialogue to produce one or more of the following personal responses to science: awareness, enjoyment, interest, opinions, and understanding.” At its core, science communication involves providing scientific information to a public that has various levels of understanding.

Ideally, researchers and other science professionals would have the ability to effectively communicate their own research to the public, but intermediate steps are often needed to make sure the message is well presented and received. However, this is often not the case. Therefore, science communication is often carried out by mediators, science communicators, or the media. In this context, mediators can be communicators, educators, or opinion-makers that have a public voice and science communication training (Burns et al., 2003). Challenges to science communication that will be examined include the use of jargon and a lack of science literacy. Both challenges increase the need for intermediate steps to communicate information between scientists and the public.

An overarching goal of science communication is to provide people with the information they need in an understandable way in order to make decisions and possibly promote behavior change (de Bruin and Bostrom, 2013). Identifying what information should be communicated and the best way to do so is essential to ensure effective science communication.

Effective science communication is especially necessary for conservation. A large portion of conservation projects rely not only on researchers, but on the public or practitioners to continue the work after the researcher has gathered data and presented results.

Conservation efforts are often very visual and have the opportunity to tell a story to the public in such a way that a large-scale difference can be made. These stories would not be told without effective conservation communication through various outlets including mainstream media. As scientists address long term issues like climate change and the associated threats to conservation and biodiversity in new and innovative ways, informing the public and garnering large-scale support through communication will be paramount to the success of these projects (Monto and Malhotra, 2011).

This article will summarize the history and challenges of science communication and examine successful methods to apply communication tactics to conservation projects.

History of Science Communication

Science communication has been occurring in a formal setting since the late 1920s and early 1930s. A group of national scientists in the United States took it upon themselves to better educate American citizens about science to enhance the public's capacity to make better decisions, live longer, and create a culture of life-long learning (Logan, 2001). These national scientists saw the proper communication of science as a true calling, believing that "a commitment to the public understanding of science not only provided immediate rewards of improving quality of life and elevating public affairs deliberations but also was perceived as integral to the elevation of democracy, culture, and the evolution of human potential" (Logan, 2001).

Science communication has been studied for almost 100 years. Even so, it was not until 1973 that it was suggested that researchers adjust their communication methods depending on how the public perceived science and their prior knowledge about the topic (Logan, 2001). This change in thinking coincided with the public becoming more involved in conservation as a social movement. The United States experienced a "golden era" of public understanding and respect of science during the Space Race (Nisbet and Scheufele, 2009). On the heels of this public engagement, the United States passed the Clean Water Act, the Endangered Species Act, and saw the social and political outcome of Rachel Carson's *Silent Spring*. This social interest in conservation required researchers to take a closer look at how they were communicating science and related outcomes. This led to jargon and science literacy being identified as primary roadblocks to effective science communication.

Science Communication Challenges: Jargon

Jargon is defined by Sharon and Baram-Tsabari (2014) as "the technical terminology or characteristic idiom of a special activity or group." When the full meaning of a word or concept is not clear, jargon limits the effectiveness of science communication by reducing the number of people who actually understand the message. Sharon and Baram-Tsabari (2014) suggest that people use language differently in different contexts. This different use of a language is called a register. Scientists have developed a scientific register, "used primarily by scientists when communicating about science with their colleagues and students." Jargon can be necessary for scientists to effectively communicate with each other but can be limiting when communicating with the public (Sharon and Baram-Tsabari, 2014). As such, it is important to translate information from a scientific register to speech that is better understood by lay people. To achieve this, scientists can be trained in effective communication with the public and journalists can be trained in effective communication with scientists.

Jargon is deeply embedded in experts and often becomes such a common part of communication that scientists no longer realize they are using it and do not remember a time before they understood the technical aspects of their research (de Bruin and Bostrom, 2013). The easiest suggestion when experts are communicating with nonexperts is to avoid jargon altogether, but this task is often more difficult than it seems. There are few standards as to what level of jargon is acceptable and the baseline understanding the audience generally has, making adjusting messages to avoid jargon very difficult (Rakedzon et al., 2017).

This provides a prime opportunity for mediators. By specially training "science communicators" alongside researchers and journalists in methods of clearly and effectively communicating with the public, the impact of science communication can be improved. Academic writing and popular science writing have different styles and purposes (Rakedzon et al., 2017). There is great potential for scientists who have also been trained in more popular writing or journalists who have a strong understanding of science to be used as science communicators.

Plaxco (2010) suggests a few simple ways to limit the use of jargon in science communications: "First, do not invent new words or phrases if there is already a commonly used word or phrase that accurately fits the bill . . . Second, if at all possible avoid using abbreviations." If jargon in the form of abbreviations is unavoidable, communicators who work in print can easily add footnotes, text boxes, or other easy-to-find methods for the audience to reference what the abbreviation means. This allows the communicator to accurately get the message across without the audience feeling like the information has been "dumbed down" for them to read. Overall, when addressing jargon, science communicators should keep in mind that the audience's understanding should be the top priority.

Science Communication Challenges: Science Literacy

Science literacy is another term that means different things in different fields. For the purpose of this discussion, Koballa et al. (1997) provide a clear definition: "A scientifically literate person is 'one who is aware that science, mathematics, and technology are interdependent human enterprises with strengths and limitations; understands key concepts and principles of science; is familiar with the natural world and recognizes both its diversity and unity; and uses scientific knowledge and scientific ways of thinking for individual and social purposes.'" This definition links back to the scientists of the early 20th century with a call to integrate science into all parts of everyday life as a way to improve society. In terms of conservation, the awareness that the natural world has both diversity and unity is especially important. This comes from an adjustment to the original definition of science literacy, which asked the public to be able to read and comprehend science-related articles. Science literacy in the modern age focuses on creating a lifelong pursuit of science as a part of everyday life (Burns et al., 2003; Koballa et al., 1997).

It is suggested that science literacy follows a continuum, from “fails to recognize words and issues as science-related” to “recognizes that science cannot be separated from the culture in which it is constructed.” This means that people with a high science literacy of key issues in various fields know where these issues came from and why they are or are not widely accepted (Koballa et al., 1997). This allows them to interpret science through the lens of their culture while understanding that the application may be different for people who are different from them. Science communicators are asked to identify where their audience falls along this continuum and change their approach accordingly.

Science literacy is difficult to measure in the general public. Most often, it is implied that compulsory education will provide the science literacy needed to get through life, but even then the standards are not common across all areas. The job ultimately falls to science communicators to ensure their message is being properly interpreted and received by a public that may or may not understand and value science at a base level. Even then, the not so simple act of communicating science may not always lead to an immediate increase in science literacy in the public (Burns et al., 2003).

Much of science literacy is also based on the value individuals place on science as a whole, and those values are often tied up in politics, religion, and other internal systems that take much more than communication to challenge. Generally, people need a base of scientific knowledge to be able to understand media messaging and cultural values surrounding science communication more explicitly and beyond the information being presented (McCaffrey and Rosenau, 2012). Polarization of scientific “beliefs” has been observed along political and religious lines for large-scale issues like climate change and evolution (Drummond and Fischhoff, 2017). There is disagreement among researchers if science literacy levels impact the likelihood of an individual “agreeing” with the science. Most researchers agree that science literacy is not the whole problem. People have predisposed beliefs depending on how they think of themselves in terms of other people and what “their group” is expected to believe in terms of certain issues (Drummond and Fischhoff, 2017). As discussed in the next section, this factor requires science communicators to tailor their message to a specific audience in order to be effective.

Useful Methods to Communicate Science

In most circumstances, people interpret new information in regards to relevant beliefs and positions they already hold (de Bruin and Bostrom, 2013). This means that all forms of science communication are most often considered in terms of whether or not the message aligns with previous opinions and knowledge. de Bruin and Bostrom (2013) suggest that “to develop effective communication materials for members of the general public, scientific experts need to understand what information people need to know”. Communication should be designed to target the most common misconceptions in a way that is easily understood and relevant to the audience (de Bruin and Bostrom, 2013).

Useful Methods: Framing

As different people interpret messages in different ways, the message can be altered to be best received by different groups of people. This broad method is called framing. Nisbet and Mooney (2007) suggest frames can solve many science communication problems: “Frames organize central ideas, defining a controversy to resonate with core values and assumptions. Frames pare down complex issues by giving some aspects greater emphasis. They allow citizens to rapidly identify why an issue matters, who might be responsible, and what should be done.”

It is often difficult for the nonscientific public to understand technical messages because of the large amount of information and media they receive daily. Scientists can fall into the trap of assuming providing technical information will clear up uncertainties within the issue. In reality, most people will not put in the effort to untangle the technical information and will instead compare the message to their preexisting values and make decisions that align with their views (Nisbet and Mooney, 2007). Ultimately, the best tool to properly frame science is to understand the audience receiving the message and adjust accordingly to address issues that matter to them.

Frames are most effective when they address an emotional connection the audience already has (Monto and Malhotra, 2011). Frames often suggest a connection between a concept that is already accepted and a new one, in a way that encourages support of the new concept (Nisbet and Scheufele, 2009; Scheufele and Tewksbury, 2007). Framing is especially useful when addressing conservation. For example, when asking farmers to conserve water, messages should be framed to link water conservation now to higher yields in the future. When asking citizens who live in a city to conserve water, the message should be framed to suggest that everyone else is conserving water so they should too. Both groups may be responsive to framing that suggests water conservation now will provide for future generations, but city residents would be less receptive to framing around higher yields and vice versa. Frames suggest what is at stake for individuals involved in an issue and why that issue matters (Nisbet and Scheufele, 2009; Gamson and Modigliani, 1989). As Nisbet stated, “Scientists and their organizations must learn to focus on framing their messages in ways that activate participation from wider, more diverse and otherwise inattentive publics, while discovering new media platforms for reading these nontraditional audiences.” Frames are extremely audience-specific and must be adjusted frequently to address issues that are current and impactful.

Useful Methods: Digital Media

Science communicators have a great advantage in modern times that was not available to their predecessors. The explosive use of social media and other online news sources has changed how the public receives information and interprets messages. Generally speaking, information still flows from scientists to journalists and then to the public (Logan, 2001). However, digital media encourages the use of informal science education and allows science communication to be included in everyday life. This allows larger portions of society to have access to information that was previously only shared in academic settings (Maier et al., 2014).

In recent years it has become relatively easy to analyze digital trends and apply that data to science communication. Internet usage has replaced traditional surveys as a way to determine the public's interest in conservation topics and encourage successful science communication. One option for science communicators is to use Google trends and similar analytics to determine what frames should be applied to audiences and mitigate the challenges caused by jargon and science literacy (Hghiem et al., 2016).

Case Studies

The following case studies showcase science communication between different communicators and audiences. These project utilized different methods and address the challenges and useful methods to communicate science to their audiences.

Communication Within a Nonprofit

This study considered “how individuals accessed information about a recent science innovation at large non-profits,” specifically The Nature Conservancy (Fisher et al., 2018). The Nature Conservancy is a global conservation nonprofit began in 1951 with a mission to “conserve the lands and waters on which all life depends” (The Nature Conservancy, 2018). This study examined communications between employees at The Nature Conservancy with a specific focus on how communication encouraged the diffusion of innovations, or “the spread and uptake or adoption of new ideas” (Fisher et al., 2018). Online communication and media were the main channels, with email correspondence encouraging employees to visit new information on their website and spread that information to the public. The researchers monitored visits on the new pages of The Nature Conservancy's website and how the type of communication used impacted the number of employees and nonemployees visiting these pages.

The study suggests that simple methods like online newsletters and webinars are effective ways to share knowledge, but a single announcement likely will not gain the maximum attention and diffusion of innovations possible. Persistent and repeated communications in the form of direct and repetitive emails that are framed in different ways to target different audiences within The Nature Conservancy were most effective to increase the views of new information on their website by both employees and the public (Fisher et al., 2018).

The authors also briefly addressed jargon, stating that “the use of common language and methods around evidence based practices can help build legitimacy, shared understanding, and trust needed for sustained collaborations” (Fisher et al., 2018). This was particularly important when encouraging employees to share science with the public. As most of the employees are not trained science communicators, presenting the information in a way that is clear and easy to understand by everyone increased the likelihood of employees being able to share the science effectively.

While most of the research on science communication is focused on communicating science directly to the public, it is also important to consider how scientists and journalists communicate science to their peers in a way that encourages more people to share science with the public. In this case study, using repeated online messages with different frames was the most effective way to increase the traffic on their website and the number of people who saw the new information that was available there (Fisher et al., 2018).

Communication From the Government to the Citizens

This study was done by the Portuguese government to “further enhance public involvement in conservation efforts and improve communication between science and society” (Vieira da Silva et al., 2017). The researchers used focus groups to learn about the general public's cognitive beliefs and normative ethics toward nature and conservation. Cognitive beliefs were observed by discussing people's knowledge and beliefs about nature, biodiversity, species, and conservation. Normative ethics were observed by discussing people's environmental ethics through expressed opinions, values, and actions. The authors found that people were generally concerned about biodiversity loss and other conservation topics but had a poor understanding of the problem, limiting their participation and support in conservation policies (Vieira da Silva et al., 2017).

The researchers used surveys of the public to determine which frames would work best to provide information that people were interested in and would lead to support of new conservation policies. While most framing is done without national surveys, this was an effective method to learn exactly what the people valued and were interested in before trying to build support for new and potentially confusing policies. By learning that people had an interest and value in conservation, the researchers could conclude that effective frames would include basic education about national conservation problems, calling citizens to care for their country and for their future.

Environmental Behavior Change Communication in High Schools

This study was done in Rocky Mountain High School as the administration, staff, and students attempted to shift their culture to sustainable education and energy conservation through behavior changes, education, and a school-wide commitment to sustainability. The researchers found that effective communication tied together the priorities of the school and encouraged success by keeping people aware of the problem and the goal. The communication from the administration to the staff and students was sustained and consistent, providing weekly updates about accomplishments and behavioral expectations to encourage participation in energy conservation efforts and create new social norms (Schelly et al., 2012).

Focus groups comprised of administration, staff, and students were surveyed to determine what communication methods were most impactful to encourage the school as a whole to reach their sustainability goals. They found that environmental leaders with a focus on science communication and framing were important for the project's success. In terms of promoting behavior change, repeated communication through multiple sources was described as the most effective method. These sources included emails to staff, face-to-face encouragement, newsletters, videos, and posters hung around the school. The posters were identified specifically as providing inspirational feedback that created a personal feeling of efficacy in individuals by providing visual updates about energy usage to compare current use with prior use, showing the staff and students that their behavior change was making a difference (Schelly et al., 2012).

Framing was also identified to be important for the success of the project. Since the participants had a wide range of science literacy and interest largely due to the age range between students and teachers, messages about behavioral expectations, knowledge, energy and resource use data, and information about social norms were adjusted for the age group they were addressing. By adjusting for science literacy and age specifically, the administration ensured that all groups felt like their efforts made an impact and they were included in the project (Schelly et al., 2012).

Conclusion

Effective science communication is imperative for successful conservation efforts. Science communication and conservation goals are generally long-term and ask audiences to compare their personal beliefs and values to what is going on in the world around them and how they can choose to make a difference or not (Burns et al., 2003). Especially as researchers address climate change and related conservation problems in new and unique ways, it is especially important to be able to communicate effectively with the public in a way that sparks a positive change (Hoffer, 2014). Science communication can be improved through the use of personalized frames and digital media.

Communicators should be aware of potential roadblocks including jargon and science literacy and should be trained in ways to avoid these problems. Anyone who tells other people about science is a science communicator, including scientists, mediators, the media, and other members of the public. Science is not just communicated from researchers to the public, but also happens peer-to-peer in various fields (Burns et al., 2003). By being aware that they are in fact communicating science to an audience that may be different from them in several ways, science communicators can improve their messages and have a greater chance at encouraging a positive change.

Abstract

Effective communication of science to end users can be challenging. Misinformation, misunderstanding and mistrust abound. It is imperative that the end user has an understanding and appreciation for science and how it can be applied to solve environmental problems. Scientists have a role to play in this discourse, but here it is argued that they may not be the primary communicator to stakeholders. Agriculture is an important consumer of scientific information and has a long-standing and well-developed relationship with scientists and advisers for obtaining and applying specialized scientific knowledge. Extension scientists and crop advisers are trusted sources of information for farmers. Their partnership leads to better distribution and application of research findings. Professional private crop advisers exist in many countries around the world including Africa, where one example shows how extension has played a key role in developing village residents to take on the role of science delivery. Similar models for partnering extension with community experts to deliver knowledge to residents have been successful in urban settings and provide a model that could be expanded into other disciplines.

Introduction

Despite decades of effort, the science community continues to struggle to clearly communicate scientific facts and elicit citizens to apply science effectively. Echo chambers (Zollo et al., 2017), that reinforce misinformation (Van der Linden et al., 2017), different perceptions of risk (Etkin and Ho, 2007) and political and social beliefs that are not supported by scientific consensus (Benegal and Scruggs, 2018) cloud numerous discussions of science. This confusion leads stakeholders away from actions that benefit them, their communities and the environment (Benegal and Scruggs, 2018). One particularly important current example of this phenomenon is climate change.

Agriculture is recognized as a critical industry that can help reduce carbon dioxide, methane and other greenhouse gas emissions that could prove instrumental in the mitigation of climate change (Robinson et al., 2018; Del Corso et al., 2015; Prokopy et al., 2015). However, changes in farming practices are difficult to implement because new practices often bring unknown risk to an industry that already deals with many uncertainties, including pest pressures, weather variability, and the influence of local and world markets. In developed countries, narrow profit margins mean farmers do not have much room for failure (Del Corso et al., 2015). Thus, narrow margins encourage farmers to stick with proven practices with more predictable risk rather than trying new practices with unknown yield and economic risks (Del Corso et al., 2015). In developing countries crop failure due to unproven techniques could mean starvation for the farmer and her family (Kansiime et al., 2018). Therefore, trust in the input and advice from an adviser is essential to implementing change at the farm level. Building this trust with farmers requires a personal relationship and understanding of the challenges that each farmer faces (Bernacchi and Wulforst, 2017; Coquil et al., 2018).

Discussions of environmental policy often involve two opposing perspectives (Etkin and Ho, 2007; Benegal and Scruggs, 2018). From their perspective policy makers and researchers viewing from the top-down identify what should or needs to be done, but stakeholders and citizens viewing things from the bottom-up identify what can be done or what is practical in light of the perceived financial and social risks involved. Power dynamics along with cultural and philosophical differences often lead to conflict and distrust between these two groups (Gaymer et al., 2014). However, there is a third group in agriculture known as crop advisers,

who currently work to help bridge the gap between researchers and stakeholders. Effective crop advisers and crop consultants are recognized as trusted advisers by farmers, researchers, and university extension (Coquil et al., 2018; Bernacchi and Wulffhorst, 2017; Robinson et al., 2018; Gabel et al., 2018). These privately employed professionals trained in science, directly assist farmers with the application of scientific knowledge and technologies to solve agricultural problems and provide more realistic perspectives on the risks involved (Ates and Sendundar, 2013). This review demonstrates that these professionals and others like them in different industries can provide critical leadership in the implementation of management practices that will benefit the environment and people locally as well as globally.

Top Down Information Dissemination

Another potential source of scientific information available to the citizens is public access journals (PLOS ONE, 2018). However, in many cases obtaining information directly from scientists is not the most efficient, practical or popular method. What are the primary methods by which people access scientific information? Family, friends, university extension and media are all potential sources (Ollerer, 2015). Education about environmental issues emanates from all these sources. Which ones are trust worthy or accurate? Is trust and accuracy the same thing? Ollerer (2015) points out that these sources can perpetuate misinformation and misconceptions even if they are well intentioned. Once again, we are faced with a divide between the top-down (scientists) and bottom-up (citizen/stakeholders). As discussed, agriculture utilizes intermediaries (extension and crop advisers) to deliver science to the end user (farmer). While there are specialists in extension that focus on agriculture, extension is not strictly targeted to support farmers. The charge of extension is to deliver science to all end users, all citizens, rural and urban, young and old alike. However, many scholars have addressed the financial and personnel shortages of extension which are likely to increase in the future (Ates and Sendundar, 2013; Bernacchi and Wulffhorst, 2017; Calvin, 2018; Clyde et al., 2018; Collins and Gaolach, 2018; Coquil et al., 2018; Del Corso et al., 2015; Kansiime et al., 2018; Ollerer, 2015; Robinson et al., 2018; Prokopy et al., 2015; Tyson, 2014).

Trusted Adviser to Practitioner (Middle Down)

Farmers have an inherent connection with plants, animals and soils and depend on healthy biology to support their family and business. Therefore, it is in their best interests to employ management strategies that protect the biological processes that they use to produce a crop. If farmers are so adept at managing biology, why then do we continue to experience large scale environmental problems associated with agricultural practices? The answer to this is at least in part due to the perceptions that management for maximum yield must rely heavily on the use of fertilizers, pesticides and soil tillage and that high yield maximizes economic return. Several of these practices can increase crop yield but are also associated with erosion and nonpoint source pollution. However, there are alternative practices such as no-till, minimum till, cover crops and crop rotation that can balance productivity and environmental risk. Innovative farmers are also experimenting with intercropping, livestock integration and other techniques that could potentially be developed and refined for broader application to address specific agricultural challenges. Difficulty arises because changing production practices involves risk, capital investment, experimentation as well as the precise application of science. Local knowledge of soils, weather, nutrient cycling, and crop adaptation are critical for successful agricultural production. Modification of existing systems that have developed over centuries requires expertise in the science of crop production as it applies locally (Del Corso et al., 2015; Robinson et al., 2018; Kansiime et al., 2018). As mentioned previously, this process also must include a realistic assessment and communication of the risk of change. In addition to traditional knowledge, agriculture continues to embrace advancing digital technology such as satellite and aerial imagery, yield mapping and plant stress indicators such as infrared and near-infrared sensing (Erickson et al., 2018). The ability to obtain and process traditional and precision management information as well as assisting farmers in applying scientifically sound site-specific solutions to solve problems is paramount in implementing on-farm change.

Role of Extension

Delivery of scientific information is the charge of university extension in the United States and many other countries (Calvin, 2018; Clyde et al., 2018; Collins and Gaolach, 2018; Robinson et al., 2018; Del Corso et al., 2015; Prokopy et al., 2015). However, budget cuts, loss of personnel and high demands on staff have led to difficulty of extension carrying out this mission. Increasingly, private advisers are filling the role of information specialists and delivering science directly to farmers (Prokopy et al., 2015; Berti, 2018). For decades extension programs aware of the many challenges they face, the limited resources available to them and the value that farmers place on private advisers have purposely developed programming to increase their influence with crop advisers to assist with this model of science delivery (Roseler et al., 1994; Schmitt et al., 2000). Extension programs have taken on the train-the-trainer philosophy (Bernacchi and Wulffhorst, 2017). Thus, crop advisers and extension have a long history of cooperation and mutual respect. Advisers go to extension specialists to obtain current science and technology training in order to provide this information to their clients (Prokopy et al., 2015; Rickert, 2001). More recently extension is viewing crop advisers as force multipliers to assist in delivering the message. Not only can crop advisers increase the amount of science delivery to farmers, they also have the skills to tailor this information to meet the specific needs of individual farming systems (Bernacchi and Wulffhorst, 2017).

Crop Advisers

Farmers list private crop advisers as one of the four most trusted sources of information (Prokopy et al., 2015). The other three are family, chemical dealers and seed dealers. In North America, the Certified Crop Adviser program (CCA) is one way for advisers to distinguish themselves as reputable purveyors of science. This voluntary certification program is administered by the Agronomy Society of America. To become certified the applicant is required to pass two agronomic knowledge tests (International and local), gain experience in the field providing advice to producers and agree to and sign a code of ethics. The required experience only includes time spent assessing crops and providing advice to farmers and ranges from 2 to 4 years depending on the level of education obtained by the applicant. Once certified, crop advisers need to complete 40 h of preapproved continuous education every 2 years to maintain certification. As of November 2018, there were over 13,000 CCA's in North America (CCA, 2018). This number of CCA's is nowhere near enough to service the needs of each farm, but it provides an existing framework that has proven successful and is quite capable of expanding. The CCA program is also recognized by government agricultural agencies in the United States and Canada as experts in the management of on-farm agricultural challenges. Some federal programs that provide funding for farmers to implement environmentally friendly management practices require the services of technical service providers. The NRCS in the United States recognizes CCA certification as satisfying some of the credentials required to become a technical service provider (NRCS, 2018). One example is comprehensive nutrient management plans. These plans are designed to reduce nutrient losses from agricultural fields and protect the environment from nutrient runoff by using soil tests, knowledge of plant physiology and weather observations to detail when, how and how much manure and other fertilizers are applied to the crop. In sensitive regions such as the Chesapeake Bay, nutrient management plans are required for manure applications (Maryland Department of Agriculture, 2019). This process helps to ensure that the farmers are receiving and applying sound science to improve on-farm and environmental outcomes.

Turkey

The challenges faced by extension are not unique to the United States. High costs and limited resources led the country of Turkey to transition its extension service from a public entity to the private sector (Ates and Sendundar, 2013). Farmers in Turkey still utilize multiple sources for agricultural information, but the private advisers are becoming the primary vehicle. Advisers in Turkey need to pass examinations and earn certificates to practice. All advisers are registered service providers and most continue to attend trainings and educational programs to further their knowledge and education (Ates and Sendundar, 2013). They interact with the remaining extension and research scientists to obtain new information and practices. This system is still being developed, but some important lessons have emerged. Interviews with advisers from the district of Antalya Province identified difficulty in securing payment for services as the most challenging problem faced (Ates and Sendundar, 2013). These advisers also identified that additional agricultural research was needed to support them and the farmers they advise. Political problems have also emerged. The wording of recent government regulations is such that advisers no longer possess prescriptive powers for pesticides. Only government officials in the Ministry of Agriculture and Rural Affairs can perform this duty (MARA, 2009). This change effectively prevents advisers from performing one of their primary duties. Advisers oppose this wording and are working toward change. They also highly recommend that wording be added to create a division between product sales and advisory services (Ates and Sendundar, 2013). Finally, during the transition many growers have been reluctant to pay for advisory services; therefore, advisers are requesting the establishment of incentive payments for farmers that employ crop advisers.

Village Based Advisers

Extension in Tanzania also faces lack of funding and insufficient personnel to service their farmers. On average, there is only one extension worker for every 2300 farmers (Kansiime et al., 2018 Hella, 2013). There is simply no way that extension can function as a primary source of information and assistance to each of these farmers. The limited extension resources are primarily used to support high value crops such as potato while one of the most important staple crops, common bean upon which over 75% of the farmers rely on for daily nourishment goes underserved (Kansiime et al., 2018). In order to address this issue, Tanzania extension has undertaken programs to train village representatives to serve as agricultural information providers (crop advisers) called village-based advisers (VBAs). These VBAs need to live in the village, work on their own and demonstrate good communication skills. The villagers themselves had an integral role in selecting the individuals that were chosen to become VBAs. One person from each of 40 different villages was selected and trained (Kansiime et al., 2018). The training consisted of teaching the VBA's improved techniques for growing common bean such as proper seed spacing and efficient use of fertilizer. They were also given improved seed varieties and tools such as planting strings to facilitate implementation of the new techniques (Kansiime et al., 2018). To test the utility of printed materials, some VBA's were given posters, pamphlets and other educational materials to distribute to other farmers. VBA's did not receive direct compensation for advice given to other farmers, but they did collect a retail markup on the small lots of seed that they sold. The main compensation VBA's received was being the first to receive training and increased status within the community. The goal was for each VBA to educate between 80 and 100 farmers within their community. The study found that VBA's primarily used face to face interactions to distribute the educational information. Techniques used included larger group farmer meetings within the village, small informal meetings and one on one on-farm training (Kansiime et al., 2018).

Village based advisers proved to be highly successful community advocates. On average each VBA connected with almost three times as many farmers as anticipated (282) and traveled great distances (10 km) (Kansiime et al., 2018). The printed materials were found across the study area even where they were not available to the local VBA. The VBA's visited each farm an average of 4.5 times during the season with some as high as seven visits. Surveys indicated that 80% of farmers highly valued the VBA's and resources that they distributed (Kansiime et al., 2018). Using the seed and techniques from the VBA resulted in some farmers doubling their yield of common bean on the same amount of land. Farmers stressed that the most important trait of the VBA's was that they possessed good knowledge that they shared by using the local language in a clear and easy to understand manner. Some farmers identified the VBA's as their primary source of agricultural information. Most of the farmers planned to continue using the techniques they learned from the VBA's as well as the improved seed varieties. Farmers did express a need for greater access to new seed and recommended that additional information on pest management and pesticide usage be provided to VBA's for distribution (Kansiime et al., 2018). The VBA model illustrates the benefits of extension working closely with local crop advisers to reach a larger number of farmers with practical applied scientific knowledge. Knowledge that proves useful to farmers was rapidly and widely adopted and shared from farmer to farmer (Kansiime et al., 2018).

France: Systems Approach

Farmers, crop advisers and research scientists all have a predisposition to manage agriculture as a collection of isolated problems with individual solutions. Research and management tactics are devised to address an individual insect pest, disease or environmental stress (Ates and Sendundar, 2013; Sanya et al., 2018). Singular problem-solving fits well into the typical scientific method of hypothesis testing. Describe the problem, generate a hypothesis that describes a possible cause, design a treatment or solution and test the probability of the hypothesis being true. This process is critically important for evaluating the effectiveness of strategies, products and methods to address individual problems. However, given that we live, work and farm in interconnected ecosystems, this model may not be the most sustainable strategy. Hypothesis testing ignores the interactions of the practice or treatment throughout the ecosystem. Interventions that treat one problem change the balance of the system often resulting in downstream effects that may or may not be predictable.

Systems or holistic management is a strategy that considers the entire ecosystem when addressing problems. For example, pest management systems can include the creation of habitat for organisms that prey on the target pest(s) (Yuksel and Canhilal, 2018). This strategy of pest management called biocontrol has been practiced for centuries and for certain pests can be an important part of the pest management system helping to make the pest control more environmentally friendly and economical. One example is the use of predatory nematodes to control soil insect larvae (Helmberger et al., 2018). The goal is that the nematode predator population will respond to the insect prey population and establish a new equilibrium where the insect no longer reaches crop damaging population levels. In some instances, this works as intended and can result in long term suppression of the pest (UC IPM, 2012). In other cases, secondary organisms respond to the new higher population of the predatory nematode and in turn reduce its population (Helmberger et al., 2018). This interconnected complexity of ecosystems makes biocontrol difficult to study and implement (Coquil et al., 2018). However, there are proven systems-based agricultural practices that provide preventative solutions for individual problems. Long-term management strategies that make use of diverse crop rotations, reduced tillage and cover crops can help to create healthier agro-ecosystems that are more resilient to pests and weather extremes (Coquil et al., 2018).

A study conducted in France of farmers during their transition to a more ecologically based agricultural system revealed the challenges faced by the farmers were more related to the application of knowledge rather than a lack thereof (Coquil et al., 2018). In order to modify the system, the farmers needed to buy, build or modify existing equipment to perform the new tasks. They also needed to adjust their management to facilitate different work periods. For example, adding additional crops or cover crops requires a longer time period of planting, thus changing the work flow and labor needs of the farm. Information needs changed and increased. Farmers needed more observations of biological interactions within specific fields on their farms (Coquil et al., 2018). This is a role where the skills of crop advisers are well suited. Observations of plant growth, plant health, pest populations, beneficial organism populations and the anticipated response of all of these to predicted weather conditions are key skills that crop advisers develop over time. The crop advisers in this study made a distinction between two different types of advice, hot versus cold (Coquil et al., 2018). Hot advice pertains to more traditional immediate discussions to address specific problems. Crop nutrient deficiencies that require corrective action are an example of hot advice. Cold advice refers to long-term systems planning. Encouraging farmers to think about schemes that will reduce soil erosion, or which crops to include in crop rotations are examples of cold advice. Both types of advice have benefits and consequences for the local ecosystem and can be directed to actions that manage not only the problems on the farm but can also have positive environmental effects (Coquil et al., 2018).

Research scientists are the primary source of information that explains our world and the processes in it. We each make personal observations daily with which we evaluate our understanding of the world we live in. Recently, there is a movement of scientists to more directly interact with people via internet blogs and social media such as Facebook, Twitter and YouTube to deliver science to the end user (Ollerer, 2015). Yet this is a minority of scientists and is not yet a major channel for citizens to obtain scientific information.

Trusted Adviser to Researcher/Policy-Maker (Middle Up)

Research is important to provide evidence-based answers to questions and problems facing agricultural production. Identifying questions and clarifying the needs of stakeholders can be challenging for research scientists (Wick, 2018; Gasch, 2019). Extension

is one of the few conduits through which practical research questions originating from farmers can be posed to researchers. Farmers often feel disconnected from researchers because there is no formal interaction between the two. It can be difficult for researchers to identify which problems apply to a broad audience versus those that apply to a vocal minority. Crop advisers bridge this gap by communicating emerging problems and assessment of scale to researchers. This helps to identify research needs which are more likely to benefit a large number of stakeholders. Crop advisers can also help researchers understand the details of practical agricultural production such as the planting, harvest and time management challenges faced by farmers (Desutter, 2018). Crop advisers are also an important source of information for policy makers (NAICC, 2018). First hand knowledge of challenges and research needs of farmers is used to support program funding on national and local levels and help elected officials prioritize funding support for critical research.

Bananas in Uganda: Are Farmers Being Heard?

The development of crop varieties is a critical component of agricultural success. This process requires cooperation of many groups along the way. First, specific challenges need to be identified. Traits that confer drought tolerance, pest resistance, crop quality and increased yield need to be identified and ranked in importance. A high-quality crop that gets wiped out by disease provides no benefit. Similarly, a pesttolerant crop that lacks flavor, nutrition or other desired traits will not be marketable.

Banana was once a significant crop in Uganda; however, the varieties used were susceptible to insect pests and plant diseases that spread throughout the country (Sanya et al., 2018). Recently, efforts to develop new hybrid banana varieties to resist these pests have been undertaken. Sanya et al., 2018, studied the actors involved in the variety development process, their linkages and influences on one another to better understand the relationships between people that ultimately result in the success or failure of adoption of a new variety. The study examined the roles of research, extension, farmers, market representatives, tissue culture and policy agencies including Ugandan government and nongovernment organizations (NGO's). Interviews, surveys and focus group meetings were conducted throughout the process of banana variety development to uncover the interactions between the parties. They found that the farmers role in influencing the final product was limited and primarily peripheral. Given the expense involved and technical nature of plant breeding, it is reasonable that the researchers and national government held a primary role in the development of the varieties. However, the lack of involvement of the farmers is concerning because if their needs and concerns are not addressed, adoption of the new varieties may not occur. One surprising finding of the study was that some NGO's were able to command an influential role in the process. It was not clear if the role of NGO's resulted in the development of successful varieties, but Sanya et al. (2018) argued that this could also result in a disconnect between what is needed on the farm and what is delivered by the variety development program. The influence analysis showed that extension was the most important linkage for farmers. However, extension agents were also largely excluded from the development process. This is yet another example of the disconnect between scientists and farmers that can have important repercussions. If the researchers fail to consider the needs of the farmers, it is possible that their efforts will be wasted on a variety that is not adopted. Once again, the limitation of extension funding and personnel limited their capacity to be involved (Sanya et al., 2018). There were areas in the study region where extension was not available to the farmers, and in some areas where extension was available, they did not have the resources to influence the process. It is encouraging to note that in these areas, community members took up the role that extension would have played (Sanya et al., 2018).

Informing Policy

The distribution of knowledge of science-based and on-farm challenges to policymakers is a critical piece of science communication. Congressional Visits Day is an annual event that is sponsored by the American Society of Agronomy (ASA, 2018). Teams of volunteers consisting of a scientist, a CCA, and a science student are assembled and trained to concisely address the information needs of legislators and their staff in regard to importance of funding for science and agricultural programs. These meetings are conducted in Washington DC at the offices of the legislators and their staff. The team uses this opportunity to communicate the biological, economic and policy challenges faced by scientists and farmers in performing research and developing management strategies. Throughout the year, members of the science and agricultural communities each develop a list of priorities that they feel need to be addressed. The team meets prior to the congressional visit to streamline the message in order to properly articulate the needs of the stakeholders (ASA, 2018).

The National Alliance for Independent Crop Consultants (NAICC) works to build strong relationships with congressional delegates and federal agencies such as EPA and USDA. They are trusted sources of "data, information and clarification for issues relating to [agricultural] businesses" (Goldschmidt, 2018). NAICC members sponsor the Crawfish Boil on the Hill event every year. This time is used to interact with, network and advise policy makers about challenges faced by farmers and agribusinesses. NAICC also closely monitors and informs members of policy discussions and proposed changes. They also provide assistance for members to contact and advise their local representatives on how policy will affect constituent farmers and agricultural businesses (NAICC, 2018).

Certified Crop Advisers and crop consultants from the National Alliance for Independent Crop Consultants (NAICC) also provide expert testimony to the US Environmental Protection Agency (EPA) when it conducts use and needs reviews of labeled crop protection products (Moser, 2019). This information can be vital to preserving pest management technologies. Recently, members testified at hearings for the insecticide chlorpyrifos (Moser, 2019). The testimony informed members of the EPA of the

alternatives available for the management of pests currently controlled with this product. Crop advisers and crop consultants provided direct information about the frequency, abundance and damage to crops caused by these pests as well as their experiential opinions about how removing the product would affect the farmers and environment (Moser, 2019). In this case, there was information that removing the product would place farmers in a position where only one type of insecticide was available, thus severely limiting the farmer and crop adviser from practicing sound IPM principles (Moser, 2019).

Citizen Connections

Citizen science is another opportunity to create connections between scientists, extension and the general public (Clyde et al., 2018). Extension personnel maintain strong connections with research scientists and can serve as the connection for citizens who wish to learn more about and be involved in research projects. Once again extension's expertise in volunteer management, budgeting and science communication and training can benefit both the researchers and citizens. The additional benefit to all is that extension can be an avenue for citizens to initiate, collaborate and help to develop research projects that address their needs (Clyde et al., 2018). An example of this interaction is the Oakland County Lake Monitoring Project in Michigan that has been in existence since 1974 (Lant, 2018). The Huron River Watershed Council trains and provides equipment to volunteers who own boats to sample water quality and screen for invasive species. These volunteers provide much more data than the agency could collect on its own (Lant, 2018). In another example, the American Ornithological Society hosts a website with content specifically for citizens who want to contribute to scientific studies (AOS, 2018). The webpage is designed to connect willing citizens with scientist. Several studies are listed, described and linked so that interested volunteers can contact the researchers and receive training (AOS, 2018). These citizen-to-scientist connections are increasing, but currently, there are few ways for citizens to propose research topics to scientists. Collaboration on citizen science projects could be one important way to accomplish this. Extension's connections with scientists from many disciplines allow them to present citizen ideas to collaborators who have the necessary expertise and interest. Equally, advisers can help citizens refine and articulate their ideas, and act as a conduit to bring their concerns and research needs to extension, scientists, and policy makers.

Hot Shots Program

The delivery of science to citizens can also utilize advisers similar to agriculture. The Hot Shots project in Denver County Colorado is one example of how extension can partner with local experts to deliver science to citizens in a mutually beneficial way. This project differs from traditional extension programs in that it is short-term (weeks-months), utilizes volunteers or part time community experts and is self-supporting. These projects address specific needs of citizens in a particular subject area. Citizen demand for a specific program initiates extension to identify community members with the skills, education and drive to deliver the program. Once vetted, extension enters into an agreement with the individual(s) to provide the training to interested citizens for a fee. Like extension partnering with crop advisers to provide information to farmers, these projects partner extension with local experts to provide the scientific information to citizens. The value of extension is that they have experience in securing funding, preparing budgets, and organizing training and volunteer events. The adviser benefits financially from fees to support the program but also socially by gaining respect and recognition from community members. These aspects mirror the VBA program in Tanzania. The citizens benefit by gaining programing that addresses their needs and interests, and extension benefits by reinforcing their value as a vehicle for the delivery of science to the public.

Filling a Need in the Climate Change Debate

Agriculture is one of the most significant industries in the world and is an important contributor to climate change though greenhouse gas emissions, land use and development and alterations of plants and animals for human needs (Howden et al., 2007). Agriculture is sensitive to changes in climate, for example El Nino/La Nina patterns affecting rainfall and temperature can account for up to 40% of yield variation in staple crops such as grains and oilseeds (Ferris, 1999). Adjustments to farming practices and energy use can provide important mitigation effects for climate change (Bernacchi and Wulfhorst, 2017; Howden et al., 2007) and resource conservation (Gabel et al., 2018).

Fossil fuel use is recognized as a root cause of anthropogenic climate change and needs to be addressed in every industry including agriculture (Robinson et al., 2018). Fossil fuels have allowed us to transport food, goods and people across the globe creating prosperity for many nations, but at the same time, we have been increasing atmospheric carbon dioxide concentration that is changing our climate with the very real possibility that we are making our planet unsuitable for a prosperous human future. Understanding and management of global climate change requires thinking and problem solving on a much higher level (Etkin and Ho, 2007).

The scientific consensus is that climate change is occurring, human activity is a primary cause and there is a need for immediate action to address it (Benegal and Scruggs, 2018). Despite the high degree of agreement among scientists (~97%), nonscientists continue to debate these conclusions (Tyson, 2014; Ollerer, 2015; Benegal and Scruggs, 2018). The distinction between weather and climate for many citizens is blurred and results in misinformation and denial and the subsequent failure to act (Etkin and Ho, 2007; Van der Linden et al., 2017).

Political and philosophical opinions as well as personal experiences and relationships all contribute to an individual's assessment of the true cause and severity of climate change. In the United States, political party affiliation is a strong predictor of agreement with climate change. [Benegal and Scruggs \(2018\)](#) showed Democrats are more likely to agree with climate change than Republicans. They also showed that statements supporting climate change made by a Republican carried more weight with all groups tested (Democrat, Independent and Republican) than if the same statements had been made by a Democrat or scientist. These strong group affiliations are also evident on social media. A study of Facebook users associated with science or conspiracy pages showed high polarization. These users commented, liked and reposted only those ideas that agreed with their existing views. Rarely did they venture out of their echo chambers. The analysis also showed that when users were faced with corrective statements, they largely ignored them ([Benegal and Scruggs, 2018](#)). Even highly compelling well-vetted arguments were dismissed. Users were also more likely to become more convinced in their stance when faced with weak statements that contradict their beliefs. This "inoculation" against differing opinions and facts that do not support preconceived ideas has been illustrated in multiple cases ([Zollo et al., 2017](#); [Van der Linden et al., 2017](#)). Inoculation messages can also be used to steel people against misinformation in public and social media. Presenting people with scientific facts about climate change and warning them that others will try to mislead them on these facts produced a significant protective buffer against misinformation. However, the research did not evaluate the longevity of the protection of these inoculation messages ([Van der Linden et al., 2017](#)). While inoculation messages can be used to protect people from misinformation, they can also be used by nefarious individuals or groups to prevent them from recognizing truth ([Zollo et al., 2017](#)).

Public consensus on climate change that mirrors scientific consensus is viewed by some as a fundamental need in order to enact meaningful change ([Etkin and Ho, 2007](#)). In the realm of national policy, public support is indeed important. The lack of public support leads to time wasted arguing over politics and results in a failure to set funding priorities that could have significant national and global impact.

However, in agriculture this need for climate change consensus is being challenged. [Tyson \(2014\)](#), argues that climate change remains a debate; one that is not likely to be resolved. Nonetheless, sustainable actions and conservation benefits that protect water, biodiversity and environmental quality have immediate and obvious value to all citizens, including climate change deniers. Even [Etkin and Ho \(2007\)](#) state, "...it makes more sense to ask, how can we relate to nature in a more sustainable and functional way...". Indeed, agricultural projects that seek to provide short-term soil and water quality benefits and protection from weather events can have a great positive impact on the environment, e.g. reducing soil erosion or preventing nutrient runoff into rivers, streams and lakes. These projects lead to many of the same actions necessary to mitigate climate change without the need for consensus, assuming responsibility or placing blame on individuals, industries or countries ([Robinson et al., 2018](#); [Tyson, 2014](#); [Gabel et al., 2018](#)). Swiss and French farmers with the help of agricultural advisers have modified their farming techniques to increase habitat to support biodiversity and reduce fertilizer and pesticide inputs without agreement on climate change. They did not agree on anthropogenic climate change, but all farmers surveyed did agree on the environmental and human goals of maintaining soil fertility, producing healthy food, treating animals with respect, using sustainable strategies and providing food security ([Gabel et al., 2018](#)).

The university extension system in the United States is a primary source for continuing education for certified crop advisers (CCA's) and because of this, there is an opportunity for extension to provide information and training directly to CCA's about climate change and practical management strategies that can help mitigate agricultural contributions. Certified Crop Advisers as a group do not show the same level of agreement about climate change as scientists ([Bernacchi and Wulffhorst, 2017](#)), yet this does not mean they cannot be agents for beneficial change. Their work is targeted at helping farmers manage challenges to production, and this includes increasing the production systems resiliency by adapting to changing weather patterns. The adaptive management that CCA's and farmers collaborate on to manage annual weather patterns includes many practices that would be implemented to manage for long-term climate change ([Bernacchi and Wulffhorst, 2017](#)). The CCA's themselves agree with [Tyson \(2014\)](#) that their daily work addresses climate change without the need to sort through the politics and misinformation to convince farmers or coworkers of scientific consensus ([Del Corso et al., 2015](#); [Bernacchi and Wulffhorst, 2017](#)).

Conclusion

Effective science communication is a vital yet difficult task to accomplish. Misinformation, misconceptions and the perpetuation of ideological barriers hamper discourse and utilization of scientific knowledge. Developing trusted advisers to bridge the gap between scientists and citizens can be an important way to deliver knowledge and implement actions that address some of the serious problems that we face, including climate change. These trusted advisers are trained in science and communication, members of the local community and skilled at tailoring scientific knowledge to address local problems. Numerous successes exist in the agricultural industry that demonstrate the importance of trusted advisers as agents of change to improve the management of farming systems. There are also examples of cooperation among scientists, extension and citizens in effectively communicating and utilizing science. These advisers can also facilitate two-way communication between citizens and scientists to establish research priorities and bring research ideas from the citizens/stakeholder to the scientists. There need not be a disconnect between the public and scientists if we amend the concept of top-down and bottom-up communication to include a middle agent, the trusted adviser.

Abstract

Storytelling is well researched and long recognized to be an intrinsic human instinct, even argued that story has influenced our evolutionary process. But until recently, storytelling diminished from scientific inquiry and presentation, placing precedence on findings. Now that storytelling with sustainability topics is enjoying greater attention in business and creative circles, is traditional narrative structures adequate in depicting modern human interaction with each other and environments? As stories about anthromes and sustainability efforts within them continue to evolve, some argue that typical narrative structures, along with messaging styles like marketing and reporting, don't adequately convey the requisite skills and knowledge needed to realize sustainability change. By increasing focus on place and characters clearly demonstrating sustainability competence in practice, struggle and success, while adopting living systems structure as a model for story structure framing, it is hoped a conscious competence is achieved by a story's audience to then realize sustainability solutions, and stories, in their own time and place. The chapter includes exemplars of sustainability stories and further reading.

Preface

If you are reading this, you are likely already interested in how humans interact and affect the planet, be it through the lens of space and patterns of anthromes, the time of the Anthropocene, the expanding premise of sustainability, or the increasing call for systems thinking and resilience. Or you stumbled upon this chapter digitally or physically, recently after publication or years removed. Either way, you are here, and it is on me as the author to write in a way that keeps you wanting to read beyond the inertia of your initial curiosity, and just like most other humans, you are likely very capable of detecting a bad or boring story or piece of writing right from the start (Cron, 2012), and can easily pass this chapter by. Still, this is an entry to an encyclopedia-style publication, meant to present prior research and knowledge in a straightforward and factual way. So, there is a back and forth of honoring the style and content while satisfying a reader's interest to read on.

If you've already spent time in the other chapters, you've gathered plenty on what we perceive as typical biomes, stretches of our planet that uniquely support life. Much of these biomes now have human fingerprints and footprints upon them, where natural systems have been interrupted and possibly irreversibly altered by human activity, heeding the nomenclature "anthromes" (Ellis and Ramankutty, 2008). As these other chapters have perhaps retained a non-biased scientific approach to human activity, or have lent themselves to explain the harm or benefit done to these corners of the Earth, human actions were driven by a want or need of something of greater perceived value than what the biome was already facilitating. Acting on those wants and needs, and the efforts to correct and remediate the consequences of those actions, is what makes conservation, sustainability, governance and consumption rife with conflict. Where there is conflict there is drama, and where there is drama, there is a story. And for much of the Anthropocene, those who told the most compelling story were often the ones who realized the vision they had for the land and the life upon it (Sachs, 2012).

Introduction

In between jaunts of graduate school and academia, I was a science reporter for a large public radio station. I caught wind of a local man who turned a dilapidated pool in his backyard into a thriving food production system. I was seeking a challenge of a story and thought I could use this as an example to somehow report on closed-loop nutrient cycles, something I was personally interested in. I

visited an open house and found dozens of people in awe of what this man and his family had done. But beyond what was called “Garden Pool,” where water and soil were arranged in a way that supported ample plant and animal food for his family, people were taken and inspired by how this modest family turned their old pool into hundreds of volunteers and an international non-profit building micro-farms in dilapidated spaces locally and in developing countries (Bernier, 2015).

I could have talked exclusively about nitrogen cycling or plant species selection, but I also spoke about this man buying a humble home right when he was laid off from a construction company and wanted an inexpensive way to feed his family. I also included how insistent he was about how many times he messed up, experimented and failed, and is always learning about what he needs to do to make the system better. I’ve interviewed and reported on national laboratories, research university breakthroughs, science policy and space technology, and this man and his pool was one of my most popular stories.

I see this story as a classic sustainability story, a person or persons responding to a challenge regarding typical sustainability concerns (food, water, climate, development, etc.) by developing requisite skills and knowledge to become a sustainability change agent and realize a vision almost anyone can do. In this chapter, I primarily use the term sustainability and less so anthromes or Anthropocene in reference to what we are emphasizing in storytelling. I do so for a couple of reasons. The first is that storytelling has recently gained enormous momentum in the sustainability field, particularly in business and with practitioners (see section: Further Reading), and is also well researched to be a tool frequently used in sustainability efforts for years (Eckstein and Throgmorton, 2003; Grace and Kaufman 2013; Ramondt and Watts, 2005). The second reason is that a story is meant to show us how and why you do what you do. We will cover that premise a bit more in detail later in the chapter, but through the lens of sustainability competence, we adopt an action oriented approach to storytelling, focusing on the capacity or ability to act and sustain a desired behavior or state of being, whereas human affected biomes are the result of action.

Why Story? Are We Wired for It?

In short, a story is “a narrative account of an event or events-true or fictional. The difference between giving an example and telling a story is the addition of emotional content and added sensory details in the telling” (Simmons, 2001, p. 31). By accommodating emotional and sensory detail, it is well researched and argued our brains are hardwired to relate to and be engaged by storytelling (Haven, 2007), where “regions of the brain that process the sights, sounds, tastes, and movement of real life are activated when we’re engrossed in a compelling narrative” (Cron, 2012, p. 4). Response triggers such as emotional engagement, relatability, and entertainment enable stories to convey critical messages simply, which are often missed by reports, news, presentations and lectures, predominant means of communicating science and sustainability (Tyler, 2009). While standard and expected in westernized science, those means often neglect innate human desires and capacities.

Biologist E. O. Wilson describes storytelling as a fundamental human instinct, a means to help convey the meaning of science and inquiry in a way the inquiry process often fails to do, or at least takes too long for the interest of most lay people (Wilson, 2002). He argues that while not every person is an apt storyteller, just about all persons can receive and possibly be persuaded by story. Jonathan Gottschall in *The Storytelling Animal* (2012) presents several social and biological means of which storytelling evolved into the human experience, be it gaudy storytelling to attract a mate, a cognitive exercise, to teach and share experiences vicariously, or to bring groups together, or control them. Gottschall notes that several evolutionists now propose the idea of religion in early human existence made societies work better by groups subscribing to stories shared within a particular church. These stories often praised prioritizing the interests of the group rather than the self, “and what they generally cause people to do is to behave more decently toward members of the group (coreligionists) while vigorously asserting the group’s interests against competitors” (Gottschall, 2012, p. 122).

For as long as we’ve made stories to bring together and distinguish groups and individuals, we’ve also made stories about the land to make sense of natural systems. Familiarity with how to work and manipulate natural systems requires time; indigenous peoples are often those who have the most knowledge and mastery of natural systems in which their people lived for hundreds if not thousands of years. The concept of traditional ecological knowledge (TEK) focuses on the in-depth “understanding that indigenous peoples have on ecosystems and their interconnectedness” (Edwards, 2010, p. 7), with generational knowledge of the land passed down through story.

On several occasions where modern analytical or western science has fallen short of explaining or predicting what ecosystems do, TEK has shown that indigenous understanding of living with seasons, species, and resources is incredibly powerful, useful, and accurate. With examples like the Balinese water temples for sustained rice yield, Tibetan people living in the harsh conditions of the Tibetan plateau and the Inuit sustaining whale hunting for hundreds of years, we have clear examples of how to use TEK and learn from it when building modern resilient communities adaptive to change (Edwards, 2010). While some would argue that reductionist western science and holistic TEK have inherent conflict, Martinez (2010) suggested there can be unity of the two approaches. Martinez argued western science most often quantifies and classifies the natural world, as opposed to listening to it. However, when science takes the time to observe and regard what TEK has been observing and acting with for thousands of years, the two are inherently successful (Martinez, 2010).

Evidence of this recognition and collaboration are emerging. The U.N. Sustainable Development Goals, The Convention on Biological Diversity, and the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services recognizes

“indigenous and local knowledge and its contribution to the conservation and sustainable use of biodiversity and ecosystems” (Tengö et al., 2014, p. 580). The result is a multiple evidence base approach to assess biomes and humans’ impact on them “where indigenous, local, and scientific knowledge systems are viewed to generate different manifestations of valid and useful knowledge” (p. 580).

While stories aim to help close the gap between westernized science and TEK, along with tapping into human’s innate penchant for story while not compromising scientific inquiry, the pace of which sustainability challenges are changing is quickening. With unintended consequences emerging from climate change, urban development, and resource mismanagement coupled with active resistance to solutions fostering wicked problems, traditional narrative structures may not serve sustainability efforts to engage, teach, and empower. To demonstrate how acting for sustainability changes both place and people, the next section describes key aspects of sustainability storytelling, an approach embracing complexity and systems structure coupled with sustainability knowledge and skills to stay relevant for as long as sustainability problems exist.

Crafting an Effective Sustainability Story

Whereas telling stories about sustainability follows more traditional methods of storytelling, using narrative structures within a sustainability context, sustainability storytelling intentionally aims to teach, convey, and empower listeners with clear and engaging examples of sustainability in action (Simmons, 2001; Pollock Shea, 2014; Amlani et al., 2016). Not only do these stories demonstrate the skills and knowledge needed to make sustainable change in our communities, but they also empower and motivate an audience member to be a sustainability change agent (Meisner, 2014).

Intent and Audience

When an idea for a story emerges, there is a bit of a vetting process to validate it, as crafting an effective sustainability story takes time. Two renowned storytelling entities, National Geographic and National Public Radio, have a series of questions they ask themselves before delving into story creation.

National Geographic Five Principles of Storytelling (As presented by Susan Goldberg, National Geographic Editor in Chief)

- Does this story make a difference?
- Does this story do what others can’t?
- Can this story be part of the conversation?
- Does this story act urgently?
- Does this story know who you are? (Goldberg, 2017)

NPR Training: Beyond the 5 W’s: What Should You Ask Before Starting A Story?

- What is my story’s driving question?
- What is it not about?
- What are my dream ingredients?
- How will I engage my audience—and hold them?
- How will I ensure the story is fair to the people and the idea it represents?
- What will the audience remember when it’s over? (MacAdam, 2016)

While stories are incredible mechanisms for teaching and having people remember details, customs, life lessons, etc., sustainability stories inherently aim to change behavior and empower an audience, rather than just covering sustainability issues. But before you can consider changing lay audience members into sustainability change agents, if you so desire, storytellers must think of who their audience is. I was in a sustainability communication workshop led by Lee Gutkind, the editor of *Creative Nonfiction* magazine and Distinguished Writer-In-Residence at Arizona State University. In it, one of his initial comments was something like “remember, your audience *wants* to walk away, they *want* to go have a cigarette or beer, they aren’t necessarily interested in what you have to say.” With this, an effective communicator must tell a good story to capture people’s attention. When captivated they will stay and hopefully share your story.

Most sustainability practitioners and academics can likely attest to this; when we give presentations, publish papers and engage the public, we are likely engaging people who are already interested in the topic. While we should not shortchange them of a good story, they are not who we are aiming to captivate (though re-inspiration helps). Rather, the folks who are not interested and didn’t show up are often those most needed to hear the story. To begin reaching those who did not show up, figure out who they are by “listening...finding out what drives them, what their priorities are, and how sustainability fits into the picture” (Pollock Shea, 2014, p. 132). Your opening scene of that picture, and even your opening line, is your only shot to frame the story and engage unaware audiences (Gutkind, 2012; Cron, 2012).

Content

Just about everything that makes a good story still serves as the foundation of what makes an effective sustainability story, particularly the 5 W's: Who, What, Where, When, and Why. The question of 'How' will be addressed a bit later. While simple in premise, many stories fall flat because they fail to adequately address these:

Who: Oftentimes organizations are highlighted in sustainability success stories, as funding for projects can dictate whole organizations. But "stories that feature the organization as the hero tend to be a bit boring or sometimes make us roll our eyes" (Amlani et al., 2016, p. 12). This tends to dilute the resonance of effort with individual audience members who are not part of the organization, and therefore may not share the same values or mission. Rather "position the organization in a facilitating role, in the background supporting the main character(s) or protagonist" (p. 12). You can have empathy for individuals. Individuals are heroes, leaders, followers, and set replicable examples (Humphrey and Adams, 2016).

What: This is two parts. The first is the issue at hand. Clearly identify the problem, first at a small scale then a large scale. Spend little time defining the problem (< 25% of your story time). Try not to put a face on it, rather describing it as the norm, resistance to change, "the way we've always done it." The second is the change you seek and solution you are creating and implementing. Is it strictly local or can it be scaled up? If it can be scaled, briefly describe what it will take to do so.

Where: While honoring bioregionalism, place-based learning, and TEK, stories can move quickly from where they are told, so where stories are set presents an interesting challenge. Stories about drought in the southwest and then stories about urban brown-field reclamation in the northeast will be inherently different. It is onto the storyteller to show and create these places in the audience's mind. It is also important to describe how these places, perhaps biomes and anthromes, affect the issue at hand and to clearly explain when sustainability efforts are unique to a place, and when efforts can happen regardless of place.

When: When can also be tricky, as many of the sustainability issues at hand don't have an end in sight. Or when a conclusion does arrive, we find more unforeseen challenges. When is important to establish not just for the era the story takes place, but how long, such as knowledge gained over generations or simple solutions that take only minutes to do, and if a specific series or sequence of events is needed (Simmons, 2001). Time can also play a central character as the pace of change becomes alarming, such as James Balog's *Chasing Ice* film showing before and after pictures of glacial retreat due to climate change (Howell, 2013; Meisner, 2014). It is also wise to make stories not appear dated as it will extend their longevity and relevance.

Why: What is the value proposition? As in, what does your audience stand to gain from sticking through with the story? Sustainability stories, while they can be entertaining, doesn't exist to entertain. The popular TEDx video and subsequent book *Start with Why* from Simon Sinek (2009) makes it clear that "people don't buy what you do, they buy why you do it." Why are the people in the story waking up and saying, "I am someone to take on this sustainability challenge?" Is it commonly shared values? Agreed upon goals? Incentives? Personal beliefs? To drive the story forward you need motivation and momentum from the characters and the audience. What is your audience's why and how can that resonate with your story's why?

Even if a story about sustainability covers all the W's, it can still fall short of what makes it a sustainability story and a needed call for action. Here are some intentional storytelling approaches that can leave an audience little to work with:

- **Reporting:** In standard reporting and journalism, the primary job is to cover the 5 W's. Having been a science reporter, I mostly had to stay within these bounds. If not, "trying to change people's minds, their lifestyles, or their politics raises ethical questions" (Meisner, 2014, p. 157). In true reporting, you must leave biases out, which means leaving out information that did not originate from the events or from the voices of those involved. A call to action here would violate this.
- **Consciousness raising/raising awareness:** It is often popular to want to raise awareness or consciousness of a topic, which is good and is often what gets an audience interested. However, "people do not change their behavior or their level of civic engagement simply because they are aware of an issue or even because they are knowledgeable about it. Among other factors, they need to feel that it is the right thing to do, and they need to see a clear path" (Meisner, 2014, p. 157). Getting your message out is hard and there are plenty of means to do it (art, videos, canvassing, protesting), but it can sometimes vilify groups or specific people, stifling solutions. In sustainability storytelling, "giving people information on how to be an effective change agent as well as opportunities to participate in actions in combination with consciousness raising is more useful than consciousness raising alone" (p. 157).
- **Marketing:** Along with having a good sense of stories, humans can also be adept sensing when they are being sold something. Stories lend themselves to authenticity through admitting challenges and fault, whereas marketing will often try to keep a more rosy picture of the discussion, though many in business are adopting storytelling (see list of further reading). Below is a dichotomy of marketing of sustainability to sustainability storytelling (Bernier, 2018);

A dichotomy of sustainability marketing to sustainability storytelling

Purpose	Marketing of sustainability	Sustainability storytelling
Who stands to gain?	Entity giving the message to sell a product or service	Individual and group audience members, practitioners
Attention paid to what?	Products or services offered	People overcoming challenges
Tone set and expectation of messaging?	"We have the solution," ease of use, success for you	Conflict, struggle, growth and solution devised and implemented

Conflict, Challenge, and Failure

Challenges serve as conflict, which is what gives drama to any story and keeps an audience engaged as the story moves forward to try and resolve the conflict. Admitting to challenge, and also portraying failure, lends a story and its characters to authenticity, creating further buy-in (Amlani et al., 2016). In typical storytelling, there are four predominant types of conflicts (though there are others):

- Person against person
- Person against self
- Person(s) against nature
- Person against society

Conflict in most stories comes from an us versus them structure, be it heroes and villains, or one story and its morals are pitted against the morals of another story, much like debating religions or political parties (Sachs, 2012, p. 20–29). We often want to deduce stories to a good versus evil scenarios, producing a binary approach to motive and plot, because challenges become easy to interpret. According to professor Tyler Cowen this simplification can typically reduce IQ by 10 points in the moment, often disregarding complexity and conflicting motives (Cowen, 2009). Capturing the challenge of sustainability can often cross each one of the four types of conflict in a single story, fostering complexity in crafting a solution. Even as individuals and groups begin problem solving, “conflicts arise between people as they identify with one another and sections of society. Effective strategies must assume controversy and build on it as a necessary part of social action” (Ramondt and Watts, 2005, p. 4).

Wanting to evoke change ultimately creates conflict, from those who prosper from the status quo, those who are hesitant on making change because of unforeseen consequences, or from those who have a different idea of how to make needed change, although sustainability transitions can be helped by alliances and co-learning between groups (Luederitz et al., 2017). Sharing stories of how one hesitated and struggled through making change invites empathy and understanding as to why you seek change (Humphrey and Adams, 2016). There is a learning curve (a challenge) for all who start making sustainability-oriented changes, and it can serve as the drama needed to overcome in becoming a sustainability change agent. “Story validates the specific circumstances people experience at the same time it invites them to look from another point of view...story invites them to creatively reframe their dilemma” (Simmons, 2001, p. 39).

Show, Don't Tell

It is critical not to tell sustainability stories, but rather show them (Amlani et al., 2016). Instead of covering each significant detail, fact and statistic, which is where presentations, papers and lectures come in, stories are more for showing the experience of the characters. This is done by increasing focus on the setting and the characters, and less on the problem or sustainability issue. This is not a simplification of the content, rather humanize the story first, then legitimize it with well-placed data. Most people have a lay understanding of the challenges sustainability aims to solve, but will likely know little of your characters and places.

This is done because it is the most immediate way your audience can envision themselves in the story. Storytellers can use descriptive but easy to understand adjectives of the environment and the characters, often describing how humans intimately interact with place and each other (Haven, 2014). In these interactions, use multi-sensory language; “I tasted, they felt, it smelled, etc.,” to tease the listener’s senses beyond just listening and watching, reinforcing memory of what to do later because “audience members use the details you provide as a substitute for their own direct sensory observations” (p. 94).

Engaging and influencing an audience, or even peers, friends, and family can be tricky, often devolving into a tell-type messaging and creating the opposite effect of resistance toward sustainable change. Also, modeling desired behavior without providing reason or describing needed knowledge and ability can often fall flat, allowing observers to question what you are doing or even reinforce mental stereotypes (e.g., tree huggers). If met with resistance, it has been shown that stories are better apt to reduce resistance rather than information heavy messaging (Grace and Kaufman, 2013).

In short, tell a story showing the desired behavior and knowledge without telling people what to do. Show competence in practice and in action, demonstrating struggle, learning and successful behavior change. When you do make a call to action, very specific and concise language works best after demonstrating what it can look like for audience members.

“Persuasive communication requires a clear description of the desired outcome and the means to accomplish that objective: Fuzzy generalities are dismissed and forgotten. Requests to take a specific—ideally, measurable—step by a specific date are considerably more powerful” (Pollock Shea, 2014, p. 133).

The How: Sustainability Competence

Clearly exhibiting or explaining how a sustainability problem is a challenge for the characters and how the individual, team, or organization will succeed is critical to sustainability stories, as we are trying to make our audiences *competent* in the topics we tell stories about. To be competent in something is having the necessary ability, knowledge, and/or skill to do something successfully. The specific abilities, skills, knowledge and attitudes for a given field are known as *competencies*, the cognitive abilities and skills an individual has or can learn in order to solve specific problems together with the related motivational, volitional and social willingness to apply the solution in a variety of different situations (Weinert, 2001).

There are many organizations that have lists of sustainability competencies (e.g., UNESCO, International Society of Sustainability Professionals), and often are categorized as:

- Knowledge: Things to know (think nouns),
- Skills: Things one can or should be able to do (think verbs),
- Disposition: The mindset and/or attitude a person should have (Friske and Larson, 2011).

However, competencies are not concepts in isolation, as competency lists tend to present. Rather, it is how well we weave them together “because sustainability problems and challenges have specific characteristics (different from problems addressed in other fields), analyzing and solving sustainability problems requires a particular set of interlinked and interdependent key competencies” (Wiek et al., 2011, p. 204). For instance, one competency for sustainability is “the ability to recognize and understand relationships; to analyze complex systems; to think of how systems are embedded within different domains and different scales; and to deal with uncertainty” (p. 207).

Sustainability stories need to weave together select skills, knowledge and dispositions to be portrayed or exhibited by a sustainability change agent in the story. There shouldn’t be too many, as that becomes unrealistic to replicate, but if an audience member walks away from a sustainability story knowing a concept or two they need to learn more about, and complementary skills on how to act on it, then they are closer to conscious competence, or “becoming aware of what you are doing so that you can adapt what you are doing whenever you need to” (Cabrera and Cabrera, 2015, p. 175).

Perhaps the main drive of sustainability stories is how Derek and Laura Cabrera describe metacognition, where there is “an increase in awareness: awareness of one’s own thoughts, emotions, and motivations, but also an awareness of how one interacts with the outside world” (p. 173). They argue an increased capacity of metacognition leads to an increase in self-awareness of learning processes, cognitive capacity and emotional intelligence. They describe a development of self-awareness on a continuum as follows (p. 175):

- Unconscious Incompetence: We don’t know what we don’t know. The audience who is unaware of sustainability and the impact of their decisions;
- Conscious Incompetence: We realize there is something to learn and are motivated. Perhaps after an audience member is led through a compelling sustainability story;
- Unconscious Competence: Practice of knowledge and skills, but not aware of mastery. This is practice, struggle, failure and growth of sustainability behavior change;
- Conscious Competence: Aware of what you are doing, and you can adapt whenever needed. Mastery of your skills and knowledge that transcends place and challenge.

In conscious competence, the notion of adaptation of your skills and knowledge to new places and challenges speaks to the notion of resiliency, a central tenet of healthy systems. With emphasis on systems thinking and resiliency, we can use systems structure to help organize and tell a sustainability story and demonstrate transformational change.

Sustainability Story Structure: Systems as Story

All stories follow structures, intentionally or not. Examples of story structures include “The Hero’s Journey,” “Nested Loops,” “The Mountain,” “3 Spheres” among others (Sparkol, 2018; Gutkind, 2012). A sustainability story is no different, though sustainability itself follows a systems structure, including elements of connectivity, complexity, emergence, feedback, resilience and other systems aspects. The problems sustainability takes on are complex, but sustainability solutions nor their messaging should be. The goal is to share simple yet strong stories that honor and navigate this complexity by highlighting resilience, revealing unknown connections, and celebrating emergence (the unknown that comes to be when interactive parts come together) as “a story weaves detail, character, and events into a whole that is greater than the sum of its parts” (Simmons, 2001, p. 31).

I teach systems thinking, and in my class I use a lot of quick stories to exemplify how systems manifest in human to human and human to nature interactions. While there are several technical considerations to systems, they are ultimately about relationships, and relationships change based on any number of factors. Stories help to capture and give reason to this, something often lost by a reductionist approach using the scientific method to try and isolate and measure an independent variable.

“A system is an interconnected set of elements that is coherently organized in a way that achieves something” (Meadows, 2008, p. 11). Stories are not much different than systems. Lee Gutkind states that parts of a story are scenes or little stories. Information flows within or in-between scenes and that the pattern scenes are organized is a frame (Gutkind, 2012, p. 218). Frames are malleable, as they “give shape to a story and keeps readers turning pages (or scrolling on screens) to find out what happens from scene to scene” (p. 218). Seeing scenes as elements of a system, and the identification and practice of competencies as the information that flows based on how they are organized, can achieve the desired awareness and empowerment in an audience.

Scenes can be intermixed, or you don’t need to start a story in chronological order, meaning you can drop characters, and audience, right into the middle of rising action to start your story. This helps to break down the typical start to finish linear design of traditional narrative structures. By adopting systems and complexity into story design, we are better able to track “vital deviations: meaningful personal experiences, creative solutions to conflict, and paradoxical truths” (Simmons, 2001, p. 251). While stories can

accommodate tangents or vital deviations, there is a point where it can be too much and exceeds boundaries. “Think of a rubber band—the more you stretch it the tauter it becomes until it breaks. So too with a good story; it can be stretched so that the reader is tantalized with heightening suspense as the writer goes off on related tangents” (Gutkind, 2012, p. 227).

One critical aspect of systems, feedback loops, helps differentiate sustainability stories from more typical stories. As opposed to someone hearing your story and being amused and possibly remembering it for some time, what is the return on telling your story? May it contribute to research? Could it result in a contract? Does it speak directly to the increase or decrease of an action in a community? Are you hoping to develop more sustainability change agents? Sustainability is ultimately an action-based field of work. With a great example of this, Jonah Sachs in *Winning the Story Wars* describes how he worked on the immensely successful viral video *Story of Stuff* with Annie Leonard (see “Examples of Sustainability Stories” section). What went from a near 60 min lecture of facts and figures describing corporate and consumer greed was translated into a 20 min animated short focused on individual empowerment and stick figures depicting everyday choices (Sachs, 2012, pp. 20–29). That video has spun off several other videos, a bestselling book, curriculum guides, a thriving non-profit, and countless speaking engagements giving the space to constantly evolve the story.

The living systems in biomes and anthromes that sustainability aims to sustain should then inform how sustainability stories work. As Annie Leonard found out, her first story was just the start, with its message constantly evolving with the change of the content it contained. But typical story narratives can be too rigid to accommodate needed change. To facilitate this, David Boje refers to living stories as means to have story not stuck to a given time or place. “A living story is all about movement...a founding of story spaces, a networking in the unfolding present, where each story is dialogically relational to another one, and must be told to tell of another social relationship...Living stories are often without beginning, and are never-ending (unlike narrative)” (Boje, 2011, p. 3). Boje then discusses his novel concept of the “antenarrative,” stories that “bridge past narratives stuck in place with emergent living stories. Antenarratives are on the move, founding spaces, whereas narratives have settled into places” (pp. 3–4). Boje describes how narratives turn spaces into places, and that living stories foster spaces where stories can be more dynamic and gives organizations better ability to shape their stories, rather than following narratives that are more linear and static (p. 4).

The systems as story structure approach is emergent, with most conversations happening in creative and business circles and some storytelling academics analyzing its application. Still, healthy systems change and adapt to their environments, as should your story structure. So, as you explore anthromes and their continuous emergence from human intervention, how would you write the story of anthromes? How would your voice and personal narrative impact the message you want to share? And to whom would you intend to share your story with? Below are examples of stories that started small and emerged into bigger, more robust stories that are still changing. While most of them are in video format, know that sustainability stories span across media mediums, and it is up to the storyteller to decide what media they are most comfortable with and what best suits the sustainability story they seek to show.

Examples of Sustainability Stories

An Inconvenient Truth (2006): The documentary film written by and featuring former Vice President Al Gore widely regarded as the film most credited to raising awareness about global warming. While mostly a presentation and talk from Gore, several produced stories were intermixed exhibiting intimate and personal experiences for audiences to resonate with. It has a sequel *An Inconvenient Sequel: Truth to Power* and fostered the launch of the Climate Reality Project organization. Available at <https://www.climateproject.org>.

Story of Stuff (2007): Starting as an acclaimed animated short, the media series *Story of Stuff*, hosted by Annie Leonard, expanded upon the roles we play as consumers and as citizens. She made the case that we are often bombarded by media and companies with the notion that we have more power as shoppers than we do as voters, teachers, parents, students, etc. By using non-identifiable stick figures, she portrayed simple actions as to how we perpetuate and can help reduce cradle to grave consumerism. Available at <https://storyofstuff.org>.

Planet Money Makes A T-Shirt (2013): A 5 part short-video services that described the extensive globalization of making a simple T-shirt and gives personal and in-depth accounts of the people who are on each step of that T-shirt’s journey to you. Available at <https://apps.npr.org/tshirt>.

A Guerilla Gardener in South Central LA (2013): Los Angeles activist Ron Finley presents a powerful and compelling message giving detailed examples of setting, action, setback and solutions for a simple action of planting gardens in blighted urban spaces. One of many effective sustainability stories presented on the TED and TEDx stage. Available at <https://www.ted.com>.

Soil Carbon Cowboys (2019): A series of short videos documenting the lives of ranchers and farmers across the south and northern great plains. Filmmaker Peter Byck of Arizona State University partners with researchers to see how large herds of cattle on open ranges store carbon back into the soil and regenerate soil health. Available at <https://carboncowboys.org>.

Anthropocene Reviewed (2019): John Green, host and writer of the popular podcast *Anthropocene Reviewed* selects two arbitrary facets of the human centered planet on each episode, reviewing them on a five-star scale. For a single person speaking on a subject for 15–20 min with no sound effects, interview subjects or music, it is an exemplar of Simmons’s vital deviations. Available at <https://www.wnycstudios.org/>.

Glossary

Education for sustainability (EfS) Education for sustainability develops the knowledge, skills, values and worldviews necessary for people to act in ways that contribute to more sustainable patterns of living. It enables individuals and communities to reflect and act on ways of interpreting and engaging with the world such that social, economic and environmental systems are not diminished for both current and future generations. This is the common form used in Australia.

Education for sustainable development (ESD) See education for sustainability above. ESD is more commonly used in Europe, and in United Nations and UNESCO policies and documents. This terminology is not widely used in Australia.

Embedding change/sustainability In contrast to ad hoc, short-term change that does not last, embedding refers to human/social/educational processes that seek to achieve broad and deep cultural change for sustainability.

Environmental education (EE) Environmental Education is a holistic, lifelong learning process directed at creating responsible citizens who explore and identify environmental issues, engage in problem solving, and take action effectively to improve the environment. Originally, its focus was on learning and teaching about and for the natural environment but is now more like EfS and ESD (below).

Sustainability (see Sustainable development) This is the commonly used term for SD in Australia.

Sustainable development (SD) Sustainable development commonly refers to human development processes that simultaneously meet human needs while also sustaining the ability of natural systems to provide the natural resources and ecosystem services upon which economy and society depend.

Sustainable Development Goals (SDGs) The 17 Sustainable Development Goals offer a blueprint for achieving a better, more sustainable future for all. They address global challenges including poverty, inequality, climate change, and environmental degradation, and how to achieve prosperity, peace and justice.

System thinking/systems change Systems thinking/systems change has emerged as the result of reductionist problem-solving approaches failing to adequately cope with the realities of complexity and uncertainty that cause a system to behave sub-optimally. Instead, it looks for links and synergies to find new ways of framing and overcoming problems, hence it is multidisciplinary and calls on a multiple of agents, relationships and power structures to contribute to a change. As a way of guiding systems change, systems thinking can address root causes of problems and issues and come up with innovative solutions that have the capacity to break through barriers and resistance.

Abstract

The concept of anthromes put humans firmly into “natural” systems. While humans have always shaped and reshaped their environments, recent history illustrates challenges, especially in Australia, this article’s focus. Against the backdrop of Australia, the article calls for effective Education for Sustainability (EfS) to address these challenges. The key role of Education in playing a significant part in the social transformations necessary is explained, along with a short history of Environmental Education (EE), Education for Sustainable Development (ESD), and Education for Sustainability (EfS), and the various international initiatives—mainly developed through the United Nations since the 1970s—that have shaped these sub-fields of Education into contemporary times. Key principals of ESD/EfS include enabling learners to see issues and solutions through the lenses of critique, particularly of our everyday ideas and practices of human development, and to develop agentic and transformative capabilities.

The article then offers an overview of a range of educational contexts—from higher education through to early childhood education—with commentary on how these sectors have responded to the challenges of embedding SD/EfS into their contexts and curricula. A case study for each context is provided to illustrate ways that EfS might be embedded into teaching and learning in order to make positive contributions towards understanding and working with biomes/bioregions for better outcomes for future generations and, indeed, for all living things.

Introduction

There is an Australian poem, “My country” by [Dorothea Mackellar \(1908\)](#), written in 1908 at 19 years of age and visiting England, while pining for Australia. The iconic second verse goes like this:

I love a sunburnt country,
A land of sweeping plains,
Of ragged mountain ranges,
Of droughts and flooding rains.
I love her far horizons,
I love her jewel-sea,
Her beauty and her terror.
The wide brown land for me!

This poem has meaning because it so aptly sums up the Australian continent with its diverse and contrasting landscapes—large inland plains and deserts cut by huge river systems, mountains that are just smallish bumps to snowcapped peaks, over 5000 km of coastline, with hundreds of islands. In this land of extremes, we have regular droughts, wild cyclones with flooding rains that bring heartache and joy in equal measure. On this land live 25 million humans, mostly hugging the coast.

Nevertheless, we need more than love for Australia. The Earth’s ecosystems on which we all depend, are under severe distress, facing unparalleled challenges brought about by disruptions to ecological, social, and economic systems. Recent reports from the Intergovernmental Panel on Climate Change ([IPCC, 2018](#)) and the World Wildlife Fund ([Grooten and Almond, 2018](#)), the Million Species Loss report, confirm that “unsustainable human activity is pushing the planet’s natural systems that support life on Earth to the edge” (2018, para 1).

[Pierrehumbert \(2006\)](#) considers climate change a “catastrophe in slow motion”; we are witnessing the effects of a 1 °C rise in global temperatures through more extreme weather events, rising sea levels and diminishing Arctic sea ice ([IPCC, 2018](#)) with global temperatures expected to rise by a further 0.5 °C to a total warming of 1.5 °C above pre-industrial levels by 2050.

Australia’s Biomes, and Landscapes Under Pressure

The consequences of global warming, especially in Australia, are grave. A temperature rise of 1.5 °C will decimate ecosystems, exacerbating social and economic disruptions and forced migration ([IPCC, 2018](#); [McLeman, 2018](#)). A recent Lancet report ([Watts et al., 2018](#)) predicts a complex and worsening array of climate change health impacts.

Climate disruptions in Australia are already sharply felt. However, it needs to be noted that there has been at least 60,000 years of continuous human settlement in Australia, so ecological change is not new, perhaps better reflecting anthromes ([Ellis and Ramanakutty, 2008](#)) vs. biomes. The first Australians, multiple tribes with distinct nations, territories, languages and cultures, have reshaped landscapes through fire and other farming methods ([Pascoe, 2014](#)) and should be recognized as the first people to reshape its ecological processes and patterns—Australia is not a land of untamed wilderness prior to white colonization. In recent times there has been growing appreciation of and respect for the knowledges, ethics and spiritualities of Indigenous peoples in Australia, who see the world differently to a Western binary between people and place. In Aboriginal and Torres Straits world views, knowledge lives in country and has agency; Indigenous people carry place within themselves; identities are bound to place. Such a fundamentally different worldview has meant very different ways of living on/with the Earth (even though we now know that Indigenous people in Australia were also agriculturists and aquaculturalists, not merely “hapless wanderers across the soil, mere hunter-gathers” (p. 229).

It cannot be disputed that white colonial “settlement/invasion” over the past 220 years has been formidable, deeply reshaping the continent, with increasingly distressing impacts at a rate of change that seems unrelenting. Here, I spell out just two of the anthropogenic challenges arising from human influence on natural ecosystems in Australia in our short 220-year history since colonization.

Sustainability and EfS

Given these challenges to our landscapes and ecosystems, serious questions arise “What is to be done”? Do we give up and leave matters in the hands of our children and grandchildren? What are our responsibilities to future generations and non-human life forms? Ignoring such questions is not an option. A starting point is how we see “development” into the future. Many are critical of the anthropocentric focus of human development especially since the industrial revolution—referred to as the Anthropocene, a proposed epoch when the human species has become dominant, having vastly reshaped the Earth on which we and all other species depend for healthy, vibrant futures. This time is precarious where children are most vulnerable to degrading social, economic and ecological conditions directly impacting their development, wellbeing and even their right to stay alive. The [UNICEF report \(2015\)](#) comments, for example, that “there may be no greater, growing threat facing the world’s children—and their children—than climate change” (p. 7). The dangers from severe weather events, increased risk of disease in unstable environments, water and food insecurities, disrupted livelihood and family displacement, as well as existing inequalities made worse where there are overlaps of high poverty with low access to essential services, become much more pronounced for children than adults.

This contrasts with Sustainability, a multidimensional concept that presents sustainability, not as environment versus people or economy, but as a mix of social, economic and environmental dimensions. Climate change, for example, impacts are environmental i.e. the adverse weather effects such as increased storms and droughts. It is social, in that people are being displaced from their homes leading to short-term disruptions and as well as longer-term effects of climate refugees. It is also economic, causing infrastructure damage and huge insurance payouts.

There are increasingly desperate appeals for radical shifts across all aspects of human development, in particular to Education, to take a more decisive role in transitions to greener, healthier and more just futures. My specific appeal is for greater understanding and implementation of EfS, a sub-field of Education, that has been around for over 40 years but needs far greater attention than is currently the case. Here, I offer a short history and discussion of EfS and its earlier iteration, environmental education. Note, in Europe and some other parts of the world, this is referred to as Education for Sustainable Development (ESD); in Australia, this field is referred to as Education for Sustainability (EfS).

What Is ESD/EfS?

While there is considerable debate about what is ESD/EfS, nevertheless, there is some consensus that.

EfS offers a vision of education that seeks to empower people to assume responsibility for creating sustainable futures. It focuses on interactions between people, and people and environments, requiring a “deep understanding of ourselves, our neighbors, or societal and cultural processes, and how we are connected with ecological systems for life” ([Lang, 2007](#)). EfS is founded on principles of both ecological and socio-political literacy that includes rich understandings of ecology, but also critical inquiry, empowerment, democratic decision making and action taking. It aims for social change that will contribute to sustainable patterns of living, across and between regions, and generations, now and in the future.

According to [Tilbury and Wortman \(2004\)](#), key characteristics of EfS include envisioning, critical thinking and reflection, systems thinking, and building partnerships in decision making. It is futures-oriented, focusing on protecting environments and creating a more ecologically and socially just world through informed action. Other characteristics include inter/transdisciplinary—holistic thinking, transformation, divergent thinking, and having a proactive attitude ([Jickling and Sterling, 2017](#)). While the concepts behind sustainability and EfS continue to evolve, it is transformative education with a focus on ecocitizenship—a concept closely linked to democracy but enriched with an ecological dimension ([Jickling and Sterling, 2017](#)).

A Chronology of ESD/Education for Sustainability

Calls for the environment to be incorporated into education agendas can be traced back to early 1970s resulting in the United Nations Educational, Scientific and Cultural Organization’s Belgrade Charter: A Framework for Environmental Education ([UNESCO, 1975](#)). The goal for environmental education (EE) was to develop:

... a world population that is aware of, and concerned about the environment and its associated problems, and which has the knowledge, skills, attitudes, motivations and commitment to work individually and collectively towards solutions to current problems, and the prevention of new ones (p. 3).

In 1977, UNESCO, together with the United Nations Environment Programme (UNESCO-UNEP, 1977), expanded this definition through the Tbilisi Declaration in recognizing the importance of systems and attention to context as necessary components of EE. The emphasis was on EE being embedded across the whole system of education and adopting a holistic approach to examining social and economic issues through an environmental lens. This Declaration called for environmental educators to be the “priority of priorities”.

Later, the United Nations (UN) World Commission on Environment and Development (UN WCED, 1987) prepared The Brundtland Report (also referred to as Our Common Future) proposing the concept of Sustainable Development (SD). Thus, environmental educators began exploring the implications of this for their education practice. Consequently, there was a shift from a focus on the environment to that of sustainable development.

The United Nations later delivered its action plan for SD, Agenda 21 (United Nations, 1992), further emphasizing a key role for education, awareness and training in sustainable development. Chapter 36 was a specific call for educators to reorient education towards SD, not as an add-on but as a fundamental shift in the purposes and practices of Education.

The next significant development was the UN Decade of Education for Sustainable Development (UN DESD), 2005 to 2014, another effort by UNESCO to encourage EFS in the face of worsening global crises (UNESCO, 2017a). The purpose of the DESD was to further integrate the principles, values and practices of SD into all aspects of education and learning. In Australia, for example, the Sustainable Schools movement was initiated via the DESD to enable and coordinate education initiatives, from early childhood education through to universities, colleges and community education, to scale up their EFS participation.

The most recent global initiative for ESD/Efs is the Global Action Programme (GAP) on ESD, part of a wider UNESCO education agenda to 2030. The GAP’s broad aim is to continue to generate attention and action for ESD across all levels and areas of education (UNESCO, 2018) with ongoing focus on reorienting education and learning to effectively contribute to SD. Action areas include the integration of sustainability into education/training environments using whole-institution approaches and increasing the capacity of educators/trainers. UNESCO’s 2030 agenda also includes 17 interconnected Sustainable Development Goals (SDGs) aimed at securing “a sustainable, peaceful, prosperous and equitable life on Earth for everyone now and into the future” (UNESCO, 2017b, p. 6). Particularly pertinent to educators is Goal 4: Ensure inclusive and equitable education and promote life-long learning opportunities for all.

While progress towards Goal 4 is yet undetermined, it is clear that the program between now and 2030 reconfirms education and educators having a key role in the realization of sustainability (Ferreira et al., 2019). Clearly, Education is seen as a catalyst for change towards the 17 SDGs. As the current Director-General of UNESCO, Irina Bokova, states “Education is key to the global integrated framework of sustainable development goals. Education is at the heart of our efforts both to adapt to change and to transform the world within which we live” (UNESCO, 2015, p. 3). However, this does not mean that educators are wholly responsible for such educational transformation—this all sectors of society must work with educators to reshape and reframe education so that it can fulfill its goal of contributing to sustainable futures.

ESD/Efs Across the Globe

While there has been significant support for ESD/Efs over the decades at the international level through UN/UNESCO initiatives, it is up to individual nations to develop their own responses to environmental/sustainability challenges. How it is implemented in Australia, for example, will be very different from how it looks in China, or in Papua New Guinea, an economically-impooverished nation struggling to emerge from its colonial past. How it is implemented in Japan or Korea where there are different historical and cultural frames for understanding relationships between people and nature—through non-Christian lenses—or how Indigenous ways of understanding human-nature relationships and how these might impact sustainability practices might be enacted, are all aspects of the considerations of Efs in different locale.

Some countries, like Sweden have whole-of-education systems approaches to Efs curriculum and have done so for a long time. Korea has come more recently to EE/Efs/ESD and invested in “green education” across the education spectrum. Australia has had a patchy policy response to Efs—sometimes a leader; sometimes a laggard. Without strong policy impetus, the fortunes of Efs wax and wane within Australian education. Nevertheless, there is a robust practitioner base in the different educational contexts, strong professional associations and networks, and Australian educators are international leaders in Efs researching, theorizing, and publishing, involved in and influencing local and the international efforts. In the next sections, I overview key features of Efs across education sectors, drawing on international and Australian research, and offering some Australian responses.

Efs in Universities

Graduates entering and leaving universities and colleges, even as little as 10 years ago, are moving into a world very different from that encountered by previous generations. Sterling (2014) comments that the future is uncertain, complex and rapidly change manifested by a bewildering array of global issues relating to economic instability, climate change, inequality, loss of biodiversity and migration being just some of the critical changes. While there is acknowledgment of the urgency for learning and teaching about sustainability within universities because of the relevance to students’ future lives, the general consensus is that Efs is far from being

wholly integrated into mainstream university curricula (Ferreira et al., 2019). Although there have been achievements regarding “greening” initiatives such as improving campus transportation, reducing waste, energy and water usage, and cutting-edge “green buildings”, as well as developing sustainability-based research profiles and capabilities, there is a disappointing focus on transforming teaching and learning. I argue that such efforts, while important, fail to harness the essential power of higher education: to inform and engage citizens in the pursuit of more sustainable modes of living.

EfS should be at the heart of higher education’s approach to the “wicked problems” of sustainability (Sterling, 2014; Leal Filho et al., 2017) and must be embedded into every facet of a university’s operations including changes in planning and policy, academic curricula, and research that facilitates environmental and social changes and must be embedded into every discipline area—Law, Engineering, Architecture, Business, Health and, importantly, Education. There is a long way to go before higher education makes the most of its [implied] mandate to educate for societal transformation and displays the leadership in EfS it should be offering. Nevertheless, there are exemplars in higher education leadership as the following case study illustrates.

Case Study: Australasian Campuses Toward Sustainability (ACTS)

ACTS is an Australian and New Zealand higher education organization that “aims to inspire, promote and support change towards best practice sustainability across all types of campuses”. It does this by “building cross-sector partnerships, bringing together sustainability educators, practitioners and change-makers to create a community for positive engagement, capacity building and impact” (<https://www.acts.asn.au/about-us/>). ACTS is focused on supporting higher education campuses to achieve the Sustainable Development Goals (SDGs) through teaching, research and operational practices. A key tenet of ACTS is recognition that education plays a critical role in delivering the global goals by providing “the knowledge, innovations and solutions to address the complex and interconnected societal and environmental challenges that lie behind the SDGs”. It does this via activities including online forums that provide a space for members to share and discuss approaches, challenges and learnings about SDG implementation. It runs annual conferences and the annual Green Gown Awards, an offshoot of the International Green Gown Awards, that cover all aspects of campus life—teaching and research, leadership, facilities and services, to how students can benefit from the quality of life in the communities around them. In July 2019, ACTS joined leading global networks and institutions in Higher Education in declaring a Climate Emergency in recognition of the need for drastic societal shifts to combat the growing threat of climate change.

EfS in Teacher Education—“The Priority of Priorities”

As noted, embedding EE into the teacher education was first identified as critical at the 1971 IUCN Conference on Environmental Conservation Education, and has been reinforced ever since. In Tbilisi in 1977, Education Ministers from around the world identified initial and in-service teacher education in EE as a priority (UNESCO-UNEP, 1977). In 1990, UNESCO-UNEP declared teacher preparation to teach environmental and sustainability education as the “the priority of priorities” (UNESCO-UNEP, 1990, p. 1).

Other important initiatives for teacher education include the UNESCO Chair on Reorienting Teacher Education for Sustainable Development, the UN DESD, and the GAP. UNESCO has supported the integration of ESD/EfS in initial teacher education through Priority Action Area 3: Building capacities of educators and trainers (UNESCO, 2017b). Continuing support by Ministers of Education highlights the important role teacher educators have as powerful agents of change, capable of delivering the global educational response needed to reorient education to achieve the SDGs (United Nations Educational, Scientific and Cultural Organization (UNESCO), 2018).

While the extent to which this recent work has progressed is uncertain, and while UNESCO’s recent reporting highlights many examples of embedding ESD/EfS in teacher education, these tend to be isolated “green patches” driven mostly by the passions and concerns of individual teacher educators who experiment with embedding EfS within their own spheres of influence, rather than wide-scale, systematic approaches (Ferreira et al., 2019). A recent review conducted by Australian researchers (Evans et al., 2017) confirms that the field is characterized by arbitrary, isolated activities such as one-off curriculum development projects, stand-alone EfS modules (UNESCO, 2017a), or mainly integrated into Science and Geography subjects (Van Petegem et al., 2005) rather than through a consistent, more holistic approach (Ferreira et al., 2006). While such efforts are commendable, a systemic approach to embedding sustainability in initial teacher education is called for actioned by EfS becoming an integral part of faculty/departmental policies, core curriculum foci and values, and clearly evident in everyday pedagogies, practices and activities. The following case study offers just one example of how EfS might be embedded into a teacher education program.

Case Study (for More Detail See Ferreira et al., 2019)

EfS has been a part of teacher education at this Australian university situated in tropical Queensland, for about 20 years, though originally as an ad hoc, final-year elective, Environmental Education for the Tropics. Transition to an embedding of sustainability approach began when the whole university underwent a “Curriculum Refresh” initiative, 2009 to 2011, aimed at repositioning itself as a “University of the Tropics” with explicit interest in sustainability, climate change and a focus on impacts on the Great Barrier Reef, literally this university’s backyard. A central aim of Curriculum Refresh was for the university to become a national and

international leader in addressing the critical challenges confronting the tropics. The University employed an integrated approach to improving environmental, cultural, economic and social sustainability via teaching, research, operations and campus management, and community partnerships.

As part of the process, the School of Education adopted a whole-of-school approach to embedding Education for Sustainability (EfS) into its Bachelor of Education (B.Ed). Recognition of sustainability as a cross-curriculum priority in the then newly-developed Australian national school curriculum, helped support this. In addition to revising the original elective, Curriculum Refresh saw two new core sustainability subjects developed as teacher education academics collaborated to embed sustainability concepts, principles, and issues, across courses in early childhood and primary majors. In 2011, at the completion of Curriculum Refresh, there were around 1250 students enrolled in the B. Ed. across two campuses, and in various modes—on campus and off campus/online.

Subsequently, with participation in a nationally-funded Embedding Sustainability in Teacher Education Project commenced in 2009, Education staff further clarified EfS as core. This expanded efforts beyond curriculum development to also be an action research project to document, monitor and study individual and collective efforts in embedding sustainability concepts and values across all Bachelor of Education classes. This led to an integrated EfS-embedded program aimed at providing teaching graduates with understandings of sustainability principles and issues and to confidently and competently engage their future students in sustainability learning.

EfS in School Curriculum

Parallel to what has happened in teacher education around the world, sustainability is also recognized in many school curricula (Buckler and Creech, 2014). For example, it is a requirement in Norway and Sweden that sustainable development be incorporated into education curricula at all levels of schooling as well as in teacher education. In China, the 15th National Congress of the Chinese Communist Party advanced sustainable development as a national strategy with ESD incorporated into China's macro-education policy agenda. China has also explored ESD/EfS practice for more than 10 years including uptake of its Green Schools program. This mirrors the history of such whole-school approaches to EE/ESD/EfS that go back to the 1970s, such as Green Schools, Eco-Schools, and Enviroschools with such movements gaining impetus with the UN Decade of ESD.

In Australia, Sustainability is a cross-curriculum priority (ACARA) and seeks to address the ongoing capacity of Earth to maintain all life. It is recognized that all learning areas such as English, Science, The Arts, Health, and Humanities, have the potential to contribute to the Sustainability priority. As such, Sustainability is included in each learning area in ways consistent with the content and purpose of the study area. Nevertheless, despite this national "mandate", Sustainability is patchily embedded into teaching and learning in schools in Australia. The demise of the national Sustainable Schools initiative, Australia's response to the UNDESD, with loss of personnel, funding and policy push, has meant that contributions to sustainability have been less than satisfactory, though there are some excellent lighthouse schools and committed teachers continuing this good work.

Case Study: The Murray-Darling River Basin and AuSSI-SA

The climate range across the Murray-Darling Basin (MDB) reflects its size, 14% of Australia's land area, and its diverse geography—from rugged mountains to flat semi-arid plains. The Basin is in the south-east of Australia and includes the Australian Capital Territory, parts of Queensland (15%), New South Wales (75%), Victoria (60%) and South Australia (7%). As Australia's most important agricultural region, it produces one third of Australia's food supply and supports over a third of the country's total gross value of agricultural production. Irrigation is the largest user of water from the River Murray system.

Water use is controlled by the MDB Authority with the aim of balancing diverse and multiple demands for water including agriculture, water supply to towns, and ensuring environmental flows for ecosystem services. Little or no flow in the Darling River due to drought and overuse of water has led to fresh water levels falling drastically. In December 2018 and January 2019, massive fish kills occurred in an area called the Menindee lakes where over 1,000,000 fish died. Species affected were predominantly bony herring, but included hundreds of golden and silver perch, as well as dozens of Murray cod, mostly large adults. The largest was 127 cm long.

Towns and cities in South Australia are at the tail end of the problems of the Murray-Darling River system, a source of great contention with severe impacts on water supply and water quality over decades, for drinking, farming and industry in this state.

Supported by the State Education Department and Department of Natural Resources Management (NRM), the South Australian Sustainable School Initiative (AuSSI-SA) provides a framework for schools and preschools to develop a culture of sustainability with their communities, with a focus on water issues. Underpinned by the principles of Education for Sustainability (EfS) discussed earlier, learning for change and developing the knowledge, values and skills needed for leading sustainable lives—over 350 schools and preschools are members of AuSSI-SA. Educational settings sign up and are then supported to plan and manage sustainability initiatives. They are offered technical advice and tailored training sessions for teachers on topics ranging from engaging with nature, food gardens for a dry climate, climate change, air quality, waste and energy matters, mentoring and support for student environment groups, and help in developing site environment management plans, setting sustainability goals and working effectively with the local community.

EfS in Early Childhood Education

As noted, the history of EE/ESD/EfS dates back to the 1970s. However, early education (Birth to the early years of school) efforts were largely missing (Davis and Elliott, 2003) though this is rapidly changing. In Australia, aligned with the more visible school-based initiatives such as the UNDES and Sustainable Schools, a handful of pioneering practitioners and a number of state-based professional networks were established to fill the void and have pushed for recognition and advocacy for ECEfS with the mantra “mainstream not marginal”. Additionally, Australian government early childhood education policy directives launched from 2008 and set against the backdrop of UN DESD initiatives have been instrumental in guiding systemic change across the early childhood education field in relation to EfS. In particular, the national early childhood curriculum guidelines (EYLF) (ACECQA, 2009) emphasizes that “children become socially responsible and show respect for the environment” (p. 32) and that educators “embed sustainability in daily routines and practices” (p. 32).

Internationally, ECEfS was first highlighted by Pramling Samuelsson and Kaga, 2008 in *The Contribution of Early Childhood Education to a Sustainable Society* (2008), and *The Gothenburg Recommendations on Education for Sustainable Development* (2008). This latter noted that “early childhood is a natural starting point for Education for SD” (p. 7) and that young children are both “affected by, and capable of, engaging with complex environmental and social issues” (p. 7). The UN Decade of Education for Sustainable Development (UN DESD 2005–2014) (UNESCO, 2017a) final report further reinforced the unique role of early childhood education in creating sustainable futures for all and outlined the expanding uptake of ECEfS across the globe over the past 15 years or so.

As a result of such state, national and international initiatives, in Australia today, ECEfS is readily visible in programs in childcare services, kindergartens, and preschools. Further, there is renewed focus on outdoor play and nature education that have been an integral part of ECE for well over 150 years. Movements such as Nature Play Australia, and growing interest in forest schools/preschools and their Australian iterations known as bush kindies/beach preschools (see for example, <http://bushkindyexplorers.com.au>) are expanding rapidly. However, while such environmental learning opportunities are to be applauded, I and others assert (and have written elsewhere) that children playing in nature is not enough to combat the unsustainable ideas and practices that reinforce unsustainability. This requires much more ambitious forms of early education. Accordingly, there are a number of ECE services that embrace whole-of-center sustainability and where children’s activist learning for sustainability lies at the heart of the curriculum.

In tandem with Sustainability in the curriculum guidelines for schools and ECE in Australia, another significant impetus for EfS lies with efforts supporting Indigenous Reconciliation and Embedding Indigenous Perspectives into curriculum. Currently EfS and Embedding Indigenous Perspectives have run in parallel rather than being enmeshed; however, this split is changing as both fields begin to appreciate their commonalities. The case study below exemplifies this emerging synergy.

Case Study (See Zerella & Thorpe, 2019 for Further Details)

An example of an ECE service bringing EfS and Indigenous education together is the Bubup Wilam Aboriginal Child and Family Centre in Victoria catering for the education, health and wellbeing of Aboriginal children aged 6 months to 6 years and their families. Here, I have drawn from the center’s website and information provided in a recent “Every Child” article. The Centre’s purpose and philosophy was developed by the local Aboriginal community, for Aboriginal people. Underpinned by Aboriginal, social justice and rights-based pedagogies, the center aims to support children to build strong and proud Aboriginal identities as their foundation for life-long learning, health and wellbeing.

With inequities in health, wellbeing and educational outcomes for Aboriginal people in Australia, Bubup Wilam requires a holistic pedagogical approach, underpinned by Aboriginal perspectives. The Centre recognizes Aboriginal people as the first owners of the land on which they live and learn, and acknowledges and pays respect to the rich history and spiritual connection of their Aboriginal ancestors. In particular, the community recognizes the importance of ongoing learning by respecting the knowledge of Aboriginal people in caring for country for over 1,000,000 years. Likewise, the community acknowledges and mourns the impact of colonization, past and present, on the destruction of the landscapes of the country and the spiritual and sacred sites of Aboriginal peoples.

Of central importance, the center is committed to supporting children in developing skills and knowledge to fight for a more sustainable and respectful future for themselves and future generations, in addressing the environmental challenges and destruction of their land and acknowledges the importance of the children’s voices in fighting for these rights. This unique “connection to country” program supports children’s spiritual connection to their world and respects the interdependence between human, animal and nature. It challenges the children to critically reflect on their custodianship rights and responsibilities. In summary, the center embraces a custodian approach to Sustainability through an Aboriginal lens, underpinned by a pedagogical that challenges Western educational theories and pedagogical approaches, and is in harmony with Indigenous beliefs and practices, and contemporary aspirations.

Conclusion

Humans have a very long history of transforming landscapes and ecosystems. Indeed, we could not have developed without reshaping and exploiting natural elements. Nevertheless, the pace of change and the extent of human impacts on the Earth’s biospheres are unmistakable (Ellis and Ramankutty, 2008) and becoming dangerous. It could be said that humans are “doing

violence” to our Earth. Our current climate emergency, the potential of 1,000,000 species to become extinct, the escalation of environmental refugees, the marginalization of first Nations peoples, and the anticipated mounting negative impacts on children and young people into the future, are nothing short of unconscionable.

While these realities are a result of many factors, education systems are not without blame; Education has contributed to our human failures in delivering societies that are healthy, sustainable, and just for our children and future generations. However, the rise of movements such as “School Strikes for Climate Change” led by Greta Thunberg from Sweden, gives some optimism. Young people are taking action, but what have we come to when it’s our school children who are calling us out? Also, I brightened up recently when I realized that many of these young people have had 15 or more years of education for sustainability, from early childhood through to high school, so perhaps our educational efforts have been more effective than I have been thinking.

Another reason for hope in the Australian context, is that polling conducted in March just prior to the national election in May 2019, shows that Australians see climate change as one of Australia’s most pressing issues (Slezak, 8 May 2019), confirming that Australians were more concerned about climate change at this recent election than at any time since 2007; 61% of voters said climate change was so serious that it should be addressed now. However, responses to the climate change question showed stark generational differences. Among Australians aged 18 to 29, 81% thought Australia should take action on climate change, even if it was expensive. Less than half, 49% of those aged over 45 took the same view. Perhaps, then, the impact of EfS over the past 20–30 years, even if patchy, has had a positive effect. Most of the elderly voters did not have the benefit of EfS.

To conclude, while EfS still has a long way to go before it is universal across the globe, it is making inroads, despite political equivocation and, in some cases, overt political undermining. However, EfS cannot be left to those who are officially recognized as teachers or educators through their qualifications. All of society needs to contribute to EfS—ecologists, botanists, social scientists, artists, technologists, journalists and media in all its forms, medical and health workers, public servants and politicians, children, young people, parents, grandparents and civil society. Particularly those of us living comfortably in richer economies, who have benefited from the practices of exploitative economic growth—be it through cheap clothes made with slave or child labor, exporting e-waste to Vietnam, habitat destruction in the Amazon to supply beef for our middleclass dining tables, or through our everyday contributions to global climate change, we are all in this complex of Anthropocentric-generated emergencies together. Essentially, sustainability is a social justice issue, and EfS is a remedy to such injustices.

Time is fast running out, however, to fix the disrupted biosystems that are our legacy to our children. If we want biomes like the Great Barrier Reef and the mighty waters of the Murray-Darling River, to be viable for all life—human as well as non-human species—for our children, grandchildren and into the next millennium, then EfS must, finally, become “the priority of priorities”. Further, we need to listen to the “the wisdom of our Elders”—our First Nations peoples across the globe who have cared for and been a part of the Earth’s biosystems for thousands of years. We all need to be educators for sustainability in whatever communities we inhabit.

Glossary

Anthroscape A human-modified landscape with substantial and permanent alterations associated with management for habitation, commerce, food or fiber production, recreation, or other human activities.

Incentive A payment or concession to stimulate greater output or investment.

Private lands Land under freehold or leasehold by individuals, not including native communal lands, and used for agricultural (subsistence or commercial), industrial, commercial or other income generating purposes.

Role-play A learning exercise designed to promote empathy and understanding of alternate views in which participants act out or perform the part of a person or character.

Wildlife Vertebrate, nondomestic animals.

Wildlife management A human decision and action that affects a wildlife population.

Abstract

Land use and conversion to meet the food and energy demands of an increasing human population is a pervasive threat to global biomes. On private lands, landowners hold the reigns when making decisions about land management. Because private lands supports biodiversity, such decisions have broad implications for biodiversity conservation. However, educational programs training wildlife biologists largely focus on public land management mirroring the public-land focused conservation movement begun in the 20th century in the United States. Wildlife management on private lands has a unique set of challenges, relative to management of public lands. Wildlife biologists working on private lands work in dynamic landscapes with uses that shift with changes in economics, regulatory regimes, and societal and cultural values. Loss of biodiversity in anthromes can be lessened if wildlife and associated habitats are managed appropriately. Yet, despite the importance of private lands for biodiversity, wildlife biologists are often ill equipped to work in these challenging landscapes. To improve preparation of wildlife biologists, we provide a case study of a modification to the learning objectives for a fisheries and wildlife degree program at the university level. Our suggestions are designed to enhance efforts to train wildlife biologists who are ready to work in the arena of private lands. Innovative, effective conservation efforts on private lands have the potential to maintain biodiversity, enhance landscape protection efforts near public lands, and create economic resilience for conservation efforts.

Private Land Conservation in Global Biomes

The wildlife conservation profession began in the United States (U.S.) during the 1900s as a movement to establish laws to protect game species and to develop a series of publicly owned wildlife refuges, parks and forests. Wildlife management has now evolved to include conservation of wildlife and their habitats found on privately owned lands. Here, we define private lands as land under freehold or leasehold by individuals, not including native communal lands (Swift et al., 2003), and used for agricultural (subsistence or commercial), industrial, commercial or other income generating purposes. Because the majority of the arable, inhabitable, usable land in the U.S. is privately owned (approximately 75%, excluding Alaska; Natural Resource Conservation Service, 2001), private lands form an integral component of the conservation landscape in the U.S. At the global scale, private lands

are likely critical for the conservation of wildlife, especially in countries where they constitute a large proportion of the landscape (Powell, 2012).

Certainly, across many parts of the world at-risk species are primarily found on private lands. For example, approximately 75% of the cheetah's (*Acinonyx jubatus*) current global range falls on lands controlled by private individuals or communal/tribal groups (Powell et al., 2017). Similarly, approximately 85% of species listed under the U.S. Endangered Species Act (ESA) spend at least part of their annual lifecycle on private lands (General Accounting Office, 1995). Therefore, it is inevitable and critical that wildlife biologists work on privately owned lands to support conservation planning and implementation. To this end, nongovernmental organizations (NGOs) and government agencies across the world have devoted many positions and money to encourage the management of private lands (MacGowan et al., 2001; Pasquini et al., 2011; U.S. Fish and Wildlife Service, 2014).

Worldwide, management frameworks to incentivize or regulate conservation on private lands vary (Powell, 2012; Kamal et al., 2015). In the U.S., the management of privately owned lands has a unique set of challenges, relative to the management of public lands that are managed in accordance with the public trust doctrine (Ciuzio et al., 2013; Drescher and Brenner, 2018). First, management decisions on private lands are made by a landowner who has invested in the land as means to a livelihood. Therefore, the use of private lands is heavily influenced by commodity prices (e.g., forest products, livestock, crops), and conservation options often lose out to other land use options that provide better economic benefits. In contrast, land use on public land is under the control of government agencies (e.g., Bureau of Land Management [BLM]). Although their decisions are partly driven by state or federal budget constraints, public land managers respond to the mission of the agency that shapes the manner of conservation actions. Therefore, conservation is often the objective on public lands, while profit from investment is often the objective for private landowners. Second, wildlife biologists who engage with private landowners have a very different paradigm for communication than do those who work with public land management teams within a state or federal agency. Third, when species or habitats of concern are found on private lands, wildlife biologists may face problems with access and coordination within the landscape of interest. Landowners may legitimately exercise their private property rights to deny or restrict access, and landowners may opt not to participate in landscape-level conservation planning. In contrast, state and federal agencies often hold access rights to large parcels of public land.

Wildlife biologists in the U.S., and indeed globally, are increasingly required to work in these complex landscapes where culture, society, politics and economics often provide the context for management decisions. Wildlife biologists may operate in supporting roles; they must work in concert with landowners who ultimately make the decision to participate in conservation programs. Given the challenges found in the private lands arena, there is a need to train students and current professionals explicitly to protect and manage the biodiversity on privately owned lands (Norton, 2000; Powell, 2010). Wildlife biologists working in privately owned landscapes need to have training which blends a suite of topics into a set of strategy and decision making skills (Knight, 1999). However, previous assessments of our profession have suggested that academic training programs in wildlife biology often fail to integrate the management techniques, policy, economics, human dimensions, problem solving and communication skills required by wildlife biologists working on private lands (Bleich and Oehler Sr., 2000; Niesenbaum and Lewis, 2003; Newing, 2010). Indeed, in an assessment of nine textbooks for wildlife management published between 1984 and 2013, we found that only three (33%) had explicit sections dedicated to discussions of private land management. Six of the textbooks (67%) provided content on legislation and policy that might affect conservation efforts on private lands, and only five (56%) contained information on economics (e.g., incentive programs or economic value of wildlife). As a result, wildlife biologists may not be adequately trained to work on private lands during the formative stages of their careers.

How might we support the efforts of universities to incorporate learning objectives to bolster training for students who will work as wildlife biologists in private lands? Here, we use selected learning objectives for the Fisheries and Wildlife degree program at the University of Nebraska-Lincoln, Nebraska, U.S. as a case example. We selected this university and program because we contribute to the curriculum committee for the program, and private lands compose 98% of the state of Nebraska (Powell, 2012). In Nebraska the NGO, Pheasants Forever and the state wildlife agency, Nebraska Game and Parks Commission (NGPC), have developed an active partnership to sponsor wildlife biologists working on private lands to assist landowners. In addition, NGPC and the U.S. Fish and Wildlife Service (USFWS) have strong in-house private lands divisions in Nebraska. Despite the private lands emphasis for wildlife management in Nebraska, we demonstrate that the local Fisheries and Wildlife program's learning objectives suffer from the historical bias toward public lands management in the wildlife management profession. We identify the training needs of wildlife biologists working in private landscapes and suggest ways that the University of Nebraska-Lincoln can modify their learning objectives to meet the requirements of private lands biologists (Table 1). In so doing, we provide a case study that can be used to improve or develop existing and future curricula aimed at training wildlife biologists for working on private lands in anthromes (Ellis et al., 2010) or the anthroscape.

What Training Do Wildlife Biologists Need?

Economics and Business

It is true that the conservation profession tends to shy away from the biases inherent in economic decision-making (Soulé, 2013), but we believe that addressing such situational decisions will largely determine the health of our planet in the future. We also know that participation in conservation efforts is strongly influenced by economic tradeoffs (Esseks and Kraft, 1986; Secchi et al., 2008). Thus, wildlife biologists must find ways to work with landowners who manage forestry, livestock, and crop production ventures if conservation on private lands is to be successful.

Table 1 Case examples of modifications that could be made to existing learning objectives for the Fisheries and Wildlife academic program at the University of Nebraska–Lincoln to provide explicit focus on learning experiences related to private lands. Current learning objectives exemplify an historic bias toward professional development for work on public lands.

<i>Area of focus</i>	<i>Current learning objectives</i>	<i>Learning objectives for private lands</i>
Economics and business	• Use mathematical concepts to represent the dynamics of socio–economic data	• Produce a business plan to financially support the conservation of biodiversity on a private forest, ranch, or farm
Human dimensions	• Describe the impact of humans as stewards, managers, and components of natural resource systems	• Describe influences on the values and actions of individuals with regard to conservation of fisheries and wildlife • Propose strategies to address conflicts between private landowners and a resource agency
Entrepreneurship and policy	• Describe the basic requirements of the National Environmental Planning Act • Differentiate the mission and management approaches of the major federal natural resources agencies	• Describe the basic requirements of programs within the current Farm Bill • Contrast approaches to management taken by a state agency, an NGO, and a private landowner who have similar conservation goals • Describe private market incentives for conservation that can be used by private landowners in the US, and compare them to incentives available around the world • Describe the process of developing, implementing and maintaining a conservation easement
Communication	• Give an organized and professional oral presentation that uses appropriate visual aids	• Propose an agenda for a public meeting of a state agency • Develop a script to be used for phone calls to obtain research access to private lands • Produce a pamphlet, radio–message, social media message, or video that summarizes results of research that can be applied on a private forest, farm, or ranch

Private landowners commonly have business plans and strategies for their lands, because their land use ventures typically represent a substantial economic investment. Thus, conservation plans for private lands cannot be developed without consideration of existing business plans, and wildlife biologists must address economic trade–offs in strategies and options. To integrate conservation options into a business plan successfully, it is fundamental that wildlife biologists understand the goals and objectives of the landowner including those associated with production, operations, and marketing, in addition to conservation. They need to be facile with the economic costs and benefits not only of conservation options, but also of all land use options if they are to succeed. This includes having an understanding of federal and state conservation programs that offer direct monetary payments and/or tax incentives and of other business expenses that may influence the willingness of a landowner to include conservation options (e.g., tax incentives for farm expenses, operation costs). Courses should provide opportunities for wildlife biology students to work with students and faculty from business, political science, economics, and marketing departments to construct business plans for private landowners that incorporate conservation options using ‘real–life’ case studies (Table 1). By interacting with private landowners whose livelihoods depend on the land (Fig. 1), wildlife biology students will better appreciate the relevance and importance of their decisions, and gain insight into the skills needed to persuade landowners effectively that conservation can provide economic benefits.

Human Dimensions

In an environment where private landowners are the decision makers, wildlife biologists must be aware of landowner values and behaviors that influence conservation decisions (Kabii and Horwitz, 2006; Selinske et al., 2015) (Fig. 2). They must also appreciate landowner attitudes and opinions that lead to conflicts that interfere with conservation efforts. Landowner attitudes toward wildlife may hinder conservation efforts when wildlife is perceived as a threat (e.g., large carnivores; Davenport et al., 2010), or may encourage conservation when the presence of wildlife may benefit the landowner (e.g., hunting, wildlife viewing; Sims–Castley et al., 2005). Wildlife biologists working with private landowners must also consider social norms in situations in which private landowners value the opinions of their neighbors and friends (Sorice et al., 2011). By understanding opinions and values of private landowners, wildlife biologists can work efficiently and effectively to achieve conservation goals.

We urge universities to include exposure to conflict resolution through challenging role plays based on real–life scenarios. Although university courses that introduce the role of human dimensions in conservation are important, they are no substitution for on–the–ground training. Of specific value would be internship programs with agencies or NGOs that provide opportunities for students to interact with a range of landowners who have different values and intentions; such experiences are fundamental to the success of emerging wildlife biologists destined to work in the anthroscape and across anthromes.

Fig. 1 Interactions between students and private landowners can improve understanding and forge working relationships, such as this conversation between a researcher and a private cattle producer in the Nebraska Sandhills region, USA. Entrepreneurship and Policy

Successful conservation on private lands requires an understanding of the role of conservation tools such as easements and financial incentives that may be pivotal in protecting wildlife and their habitats. Farm subsidy programs, mitigation techniques, and tax-incentives aimed at individual landowners have been used effectively as incentives to encourage conservation on

private lands (Norton, 2000; Feng et al., 2013; Smith et al., 2018). By combining incentives with education, even more controversial conservation techniques such as prescribed burning can be encouraged (Edwards et al., 2014). Yet, these tools sometimes fail because economic realities (e.g., prices of commodities) force private landowners to opt out of incentive based conservation programs. Therefore, wildlife biologists working in private lands need to diversify their methodology and use other tools (Powell, 2012). Appropriate tools may include incentives provided to the community as a whole that encourage community-level involvement in natural resource management decisions (Bajracharya et al., 2005; Nelson et al., 2010). Landowners can also be encouraged to manage their land to maximize biodiversity and wildlife viewing opportunities in return for economic benefits derived from ecotourism (Stem et al., 2003; Sims-Castley et al., 2005). Similarly, agroforestry schemes that combine agriculture and forestry to create an integrated and sustainable land-use system for the benefit of both landowners and wildlife can be promoted (Bentrup, 2014). Not only do multipurpose systems provide resources for humans (e.g., food, fiber, and energy), but they also provide habitat for wildlife. An understanding of these tools and examples of how they can be implemented through the use of case studies are critical to include in training wildlife biologists destined to operate on private lands (Table 1).

Communication

Perhaps most importantly, students destined for careers as wildlife biologists on private lands must be able to communicate effectively and build solid relationships with a diverse range of private landowners with different needs and values (James, 2002; Jacobson, 2009). Wildlife professionals need working relationships that are based on honesty and trust, especially in situations where landowners feel over-regulated and are concerned that their livelihoods are threatened by bureaucracy. Ultimately, failure to communicate effectively and work cooperatively with private landowners will hinder conservation.

Through effective communication, conservation-based education and outreach, including personal conversations, classroom based teaching, and regional dissemination of information through media (e.g., television, newspapers) can be used to inform, encourage and stress the importance of conservation to private landowners (Horwich, 1990; Lemke et al., 2010). These tools have proven successful in the hands of wildlife biologists working on private lands worldwide, but the applications are site-specific, and each requires knowledge of basic strategies and planning.

We believe that universities are doing a good job at providing opportunities for wildlife biology students to develop basic oral communication skills. However, seldom do they provide opportunities for students to participate in practical communications with landowners and wildlife professionals. We echo the call of Powell et al. (2009) for agencies and NGOs to work with universities to develop training programs for the next generation of wildlife biologists. Students should have an opportunity to interact with landowners during their training (Table 1).

Many of the skills needed for effective education and outreach can be gained through communication courses. However, of additional value would be a course in which students produce outreach materials based on land management practices that promote biodiversity such as rotational grazing or prescribed fire use (Table 1). Opportunities to disseminate materials and receive feedback would allow students to gain firsthand experience with working with private landowners.

Conclusions

Training programs for wildlife biologists should directly address dynamics of private lands in the anthroscape for conservation success across biomes of the world. However, we do not advocate widespread curriculum revision with new courses. The tools for private lands conservation can be taught through modifications to current curriculum, short-courses, continuing education credits, certificate programs, internships, externships, and involvement of government agency and NGO personnel in the classroom.

Wildlife biologists who work on private lands are faced with a seemingly impossible task. The trend of land use changes on private lands and the associated threats to biodiversity will only increase in the future as the human population grows. Underlying economic and political conditions may force increased use of private lands for food production, energy acquisition, industrial output, and human habitation. We can predict that conservation will lose in many of these scenarios, unfortunately. We believe that the basic ingredients for the solution to the problem lies within the private lands landscape; the loss of biodiversity can be lessened if wildlife biologists are better equipped to work in this changing, challenging landscape. Effective conservation efforts on private, working lands have the potential to maintain biodiversity, enhance landscapes surrounding public lands, and create economic sustainability of conservation efforts (Norton, 2000; Powell, 2012). Universities must continue to adapt curricula to provide directed training to students who plan to join the growing ranks of wildlife professionals working in private lands.

Abstract

Younger generations will face known and unknown challenges in a complex, changing world. Frameworks like anthromes and coupled human and natural systems have helped refocus conservation issues in a way that makes space for human contributions. Young conservationists may find success with not only ecological tools and training, but also with interpersonal and relational skills, such as effective communication. Combining personal narrative inquiry with a literature review, I propose that a promising future in conservation practice involves adaptability (individually and as a field), diversity, and localized grassroots efforts. In particular, I describe: exercising flexibility in where we work (e.g., a focus on populated anthromes and multifunctional landscapes) as well as what a conservationist may look like, considering how different types of skills can contribute to more innovative problem-solving, and considering the role of values and experiences in shaping conservation behaviors and engaging non-scientific audiences.

What does the future of conservation look like? Conservation has deep roots in principles and theory, but is dynamic and innovative. Our world is constantly changing. Our science must shift and keep pace so our actions are based on current understanding. It can take careful scrutiny to recognize we are in the middle of a transition. We develop new methodologies at such a quick rate that it can seem like we barely finish validating current approaches and technology before exploring new ones. The curse and the blessing is that we, as young conservationists, have more and more to catch up on but also a chance to set the tone for the future. Like many, I am comparably new to the field, but have witnessed a transition of themes and jargon. We have moved beyond the view of nature as a separate entity and embraced the interconnection and interdependence between human systems and nature (CHANS; Liu et al., 2007), describing world anthromes (Ellis et al., 2010). The future of conservation is going to be marked by adaptability in how and where we work, heterogeneity and inclusivity in values and skills, and local grassroots engagement.

Adaptability is a strength of this discipline. Structured Decision Making and the new Open Standards for Conservation were not the first conservation planning frameworks, nor will they be the last, but they are key tools that allow for re-evaluation (Schwartz et al., 2018). Science is inherently iterative and embraces change if A leads to C—instead of B, as expected—multiple times. When we behave this way ourselves—adjusting where we work and what we focus on—this is also a strength. Although the wheels of change can be slow to turn, scientists know that we must be flexible when a preponderance of evidence indicates an old framework is no longer adequate. Those of us early in our career may have more mobility to shift our priorities (e.g., to populated anthromes), but we must have the opportunity to do so. Novel problems require innovative solutions, and I think we will see more as younger generations bring forward creative and resourceful ideas.

Diversity is a critical ingredient in resilience, and our conservation will be stronger in conversation with those of different backgrounds. In personal as well as professional settings, being inclusive means valuing those with different career trajectories. One person's skills may be in quantitative or computational analysis, another's in field identification, and another's in public extension, but they may all deserve mentorship and opportunities to practice conservation. STEM initiatives have made significant progress in the US (DeJarnette, 2012) but kids should know that doctor, engineer, and physics teacher are not the only jobs available in science and math. Additionally, conservation groups can focus on common values using relational, human-centric messaging to reach and unite different populations.

Local engagement paired with sound research will have best practical successes. Place-based solutions driven by strong and engaged communities may be of increasing importance in future years. The global reach but localized, context-dependent approach of both the Nature Conservancy and PeaceCorps speaks for itself. Incorporating stakeholders is a method to increase support, and ultimately efficacy, of controversial conservation strategies (Gregory, 2000; Knight et al., 2006). Engaging volunteers for a day of service in their area has merits beyond the work itself—those investments can be transformational and long-lasting. Small, grassroots changes scale up. Intentional regional conservation planning (as in the US's Landscape Conservation Cooperatives framework) can address the specificity of local issues in a way that still allows for coordination between regions. (Examples of such scenario planning are ever more comprehensive; Karner et al., 2019).

These are three broad priorities for the future of conservation research and application. They reflect scholarly and personal experiences: adapting to anthromes as a grounding for effective conservation, embracing heterogeneity in skills and values in conservation training, and engaging stakeholders outside academia, including private landowners and local nonprofits. In each section, I use narrative inquiry to weave together personal reflections and professional lessons into an outlook of millennial conservation.

Adapting to Anthromes: A Conservationist's Evolution

Anthromes are one of our many improved tools for approaching conservation problems (e.g., Gibson and Quinn, 2017). Anthromes organize our thinking around multifaceted and dynamic CHANS and identify solutions for complex problems, “owning” our role as shapes of current and future sustainability challenges (Fuentes and Baynes-Rock, 2017). Societal systems are deeply embedded in directions for conservation science (Sutherland et al., 2009; Fleishman et al., 2011). It is striking that, of the 100 conservation questions of our time (Sutherland et al., 2009), each of the 12 overarching categories is influenced by human inputs, caused by human processes, or directed by human policies. In particular, ecosystem-related questions incorporate anthropogenic effects and ask “what, and where, are significant opportunities” for conservation, including among intensively managed landscapes (Sutherland et al., 2009). The first three priority questions in Fleishman et al. (2011) explicitly consider human needs in relation to conservation goals, and the next five consider how human management activities might be adjusted, but not ceased, to improve biodiversity outcomes. Most of these challenges not only acknowledge human transformation of ecosystems but also ponder how to proceed with conservation objectives without sacrificing human mainstays like agriculture, timber production, and economic growth (Fleishman et al., 2011). Given how deeply ingrained and accepted human needs and activities are in these kinds of guiding documents, it seems clear researchers are working in the Anthropocene.

I had no big picture like global conservation questions or anthromes in mind when I began doing conservation research; I jumped into research because it was fun and I had great mentors. Nonetheless, those experiences shaped my perspective of the discipline, piece by piece building and rearranging a framework of conservation thinking that ultimately does, and *must*, include people. The growth and opportunity that resulted for me individually, and for the field as a whole (e.g., from general biology to applied ecological research on multifunctional landscapes), demonstrates why it is important that conservation remains adaptable and flexible.

In my first year of research I was taught my first lesson in ecology: the whole landscape and community are the keys to understanding a species. To study puma, we studied scat and carcasses of prey, in both choice and poor habitats, but all in what could be classified as wildland anthromes. We were ecological detectives; employing tools and research designs to cobble together life history information. We read trophic cascade books and learned mule-packing, knot-tying, gun-cleaning, and how to survive during long days in rugged, remote wildlands. I fancied myself a kind of renaissance naturalist, a daughter of Aldo Leopold. The Sand County spirit was truly in me—entrancingly so.

I spent three seasons this way. But even working in the beautiful ecosystems of New Mexico, we were not free from the influences of the human population. We learned the perils of discussing the conservation of Mexican gray wolves in public spaces. A challenge of conservation in southwestern states is public and private land grazing rights and the division among stakeholders. As guests, we ought not rub resident ranchers and farmers the wrong way with our ideas of conservation of predators. We worked in human areas, fitting carnivore biology in as well as we could among the regular demands of residents, refuges, and air force bases. These stakeholders had to agree if we wanted to do anything for the big cats other than track them. Even in the land of desert mountains and ponderosa pine forests, nature was both “out there” and in here, with us. I found the proximity of contentious human interests and wild animals to be unwelcome. How do we make the space for conservation efforts within a human world?

I will never stop dreaming about those idyllic landscapes, but I was struck by reality. Literature like *Crow Planet* and *Coyote at the Kitchen Door* and courses in sustainability science and policy diversified my exposure to conservation. I read about the mismatches between biodiversity and where ecologists work (Miller and Hobbs, 2002) and currently protected areas in the United States (Jenkins et al., 2015). I absorbed prioritization papers like “The top 100 questions of importance to the future of global agriculture” (Pretty et al., 2010). Perhaps it was an inevitable result of a liberal arts education that I would be seeking something else besides traditional wildlife biology, or perhaps I simply mirrored changing management attitudes (Manfredo et al., 2018). Regardless of the reason, I came to understand that we cannot all be Yellowstone biologists. What about the nature around us at home? We cannot all travel to pristine “semi-natural” pockets of the globe; in fact, there is a need to study flora and fauna in more populated anthromes (Martin et al., 2012).

Conducting research closer to home, we understood the socioeconomic forces shaping the landscape and had a fuller picture of the environment and its players. To me, like many, urban ecology was not objectively as enticing but I was shown I had a ready-made backdrop for a natural experiment. Our case study was a rapidly developing southeastern city in a temperate forest zone, flanked both by agricultural counties and by a natural escarpment with more land protection activity. We had a spectrum of green spaces to compare, from urban parks to empty lots in suburban neighborhoods, patchy small-scale farms, and finally private conservation easements and nature reserves. With vast structural and compositional differences, which patches represented wildlife habitat? The question I took up then and still have not relinquished is this: what is the value of non-protected or so-called marginal spaces to wildlife? Thinking in terms of anthromes (e.g., Ellis and Ramankutty, 2008) allowed me to incorporate patterns of human land

use into the answers. Temperature forest areas became residential woodlands (Ellis et al., 2010), distinctions which revealed differential conservation potential (Wood and Quinn, 2016).

I learned that study species do not have to be the stuff of dreams. I did not feel the same awe from chickadee songs that I felt handling puma. However, saying I just wanted to count birds was my ticket to conversation with park managers, farmers, and retired property owners. Backyard bird talk is a great equalizer and it granted me access to land, which forged connections between the community and our research. I saw that avian diversity and abundance were outputs, reflecting a number of habitat quality inputs, including the spatial influences of the surrounding human population.

I saw that the habitat patch and matrix were shaped by human decisions into anthromes with conservation potential, and that human activities must be factored into habitat management. That Upstate South Carolina project morphed from traditional bird surveys to audio sampling to anthropogenic effects on bird vocalizations (Ernstes and Quinn, 2015) to a comparison of public versus private land populations (Quinn and Wood, 2017) to—beyond my tenure—socio-economic evaluations of ecosystem services (Quinn et al., 2015) and zoning governance efficacy (Brown and Quinn, 2018). It was intuitive to move from analyzing the ecological context of a forest patch to the socio-environmental context.

I was encouraged by the practicality of studying rapidly developing landscapes because it seemed likely we would have more and more of those. I shifted from studying the urban-to-rural gradient to looking at multi-objective/multi-functional landscapes. I studied avian communities affected by private land management decisions on lands used primarily for timber production. I noticed that the time I spent interacting with landowners was disproportionately greater than the time I spent surveying birds, and that those tree farmers and easement landowners were the ones driving the conservation work. Their willingness to engage was what would really matter for my study. How else would EQIP and other Farm Bill practices I studied be implemented, or conservation acres get protected, but with private citizen actions? I realized outreach and contextual awareness of socioeconomic behaviors are critical to putting conservation into practice beyond protected lands.

I also spent some time in land conservation and stewardship. As I inventoried natural resource values of properties going under permanent protection for a land trust, I faced different strategies of conservation. Of course I believed in promoting large swaths of public parks and national forests; sufficient habitat and connectivity are key to biodiversity conservation (Soulé and Terborgh, 1999; Trombulak and Baldwin, 2010). But what is the influence of private land to regional conservation? In the American southeast, much more of our forestland is privately owned and managed. Surely the decisions that are made daily on all those individual parcels accumulate to affect collective conservation outcomes. That is why my land trust was interested in safeguarding land it believed would serve as buffers for fragile natural communities. I observed firsthand the success of encouraging the small private landowner to make an impact, as well as of regional conservation planning and multi-stakeholder collaboration.

These stepping stones in my development as a conservationist paved the way for a perspective which readily accept that people are relevant to our conservation approach. Most systems we work in are transformed to some extent—not intact, natural communities defined primarily by vegetation and climate but rather changed and novel ecosystems with unexpected dynamics (Ellis and Ramankutty, 2008). Our research priorities must be updated to reflect our reality and practice must catch up with research (Pressey et al., 2007). Humans make up many of these landscapes, and so they must be a part of the study and solution (Knight et al., 2006; Fuentes and Baynes-Rock, 2017). Conservationists of my generation may be able to answer some of these challenges with anthromes in mind. For example, the anthromes approach also adds value to conservation scenario planning involving both biodiversity and ecosystem services, and aids in the identification of strategic trade-offs (Gibson and Quinn, 2017). Anthromes hold potential to facilitate connections between conservation goals and policy, especially in private and working lands (Martin et al., 2014). I have witnessed actionable steps to this effect in multiple anthrome types in the American southeast, including with carbon credit payments and USDA Farm Bill incentive programs. Undoubtedly we will see more.

Embracing More: Inclusion and Diversity

Conservation groups are including people in their mission statements and marketing in intentional ways. From the following examples, it is clear that anthromes are moving from conservation science to practice. In this application, values can be used as tools to connect seemingly disparate ideas and people. In that unity, we will find conservation success.

Enjoying the benefits and services of protected areas is not new, but recent language draws people into the equation perhaps more explicitly than in the past. For example, regional land conservancies highlight the interdependency between nature and people—“wonderful places” are protected because they are where we “live, work, and play” and they “have the power to change our lives” (Conserving Carolina). In rebranding, Conserving Carolina elevated the role of its constituent community by changing their slogan from “Saving the Places You Love” to “For Nature and People. Forever.” Human enjoyment has moved into the Southern Appalachian Highlands Conservancy’s mission statement via the “connecting people to land” initiative. Overall, these trends seem to be a departure from “leave it alone” sentiment of the 20th century, from Wilderness-Act-era restrictions of certain activities on protected land and accusatory imagery like Smokey The Bear and the 1970s “Crying Indian.” Rather than being inaccessible and roped off (for its protection), such organizations envision people interacting with nature (for our enjoyment)—in a respectful and responsible way, of course. Language such as “Find your Park” (Park Service) is invitational, reflecting that personal connections to landscapes are not only acknowledged but encouraged. A similar effort is reflected in academia.

Socio-environmental ties are more notably present in conference themes and keynotes. The 2018 North American Congress for Conservation Biology continued a theme of integration and connections (“Connecting the Urban to the Wild”) from 2012 meeting,

"Bridging the Gap: Connecting People, Nature, and Climate." Others have buzzwords for nature such as "frontiers" or "gateways," and themes of change are recurring (The Wildlife Society, Ecological Society of America, Society for Conservation Biology). The 2019 Ecological Society of America meeting theme is "Bridging Communities and Ecosystems: Inclusion as an Ecological Imperative." The description indicates that ecology must reflect how dynamic and diverse the community is and ought to be, with reference to: transformations, "connect[ing] ... disparate landscapes and subdisciplines," "diverse perspectives," "new techniques," and "interdisciplinary collaborations." The shifting language indicates a potential for connections and experiences—relational and eudaimonic values (Chan et al., 2016)—to improve conservation engagement.

Continuing to integrate principles from other disciplines (e.g., public health in Pullin and Knight, 2001) should help maximize conservation options. In practice, this includes understanding human behavior and decision-making using social science, incorporating the social and economic pillars from sustainability science, and leaning on industry solutions (e.g., improving habitat with "green" and "gray" infrastructure). But this kind of integration and inclusivity should not stop at interdisciplinary efforts.

The gratifying thing about conservation work is that it takes—and indeed will require—all kinds.

Where does a conservationist come from? There is no one way into this field and perhaps no one way forward. Yes, more often than not, conservationists played in the woods and turned over rocks, looking for small life. We had a special place outdoors to explore. But not always. Our trajectories do not all match those of famous naturalists. Sometimes we reach this profession (or passion) because of unexpected opportunities. Could a conservationist not come from another profession with a desire to apply their skills to environmental causes? Someone with a strong chemistry or physical science background may have innovative solutions to offer. Environmental legislation and community organizing takes nonscientific leadership. An ability to teach effectively can be leveraged to instill a wider stewardship ethics and influence far more lives than the standard readership of an academic article. I have learned that conservationists look like many things, and there is room at the table (or in the field) for many people, backgrounds, perspectives, and skill sets.

In deciding what I wanted to be when I grew up, I had a Goldilocks-type meter that indicated which work was not quite right for me. I did not really want to be a veterinarian, I just wanted to work with animals. For a period in my childhood, I vowed to be an escapist "wild girl" who lived in the woods with animals. Like many, I thought of nature as romantically "out there," and at odds with human civilization. It was dichotomous; one or the other, and initially I preferred the one with fewer people. I did not know about wildlife biology—beyond the unbelievable Jane Goodall or TV personalities like Steve Irwin—and ecologists did not frequent high school job fairs. By the time I was in college and had elective courses in my pre-veterinary biology major, I realized some combination of wildlife biology, landscape ecology, and conservation science came close to ticking all my boxes. My inner wild-girl-in-the-woods was almost satisfied when I tracked puma in New Mexican mountains, but it had not all clicked yet—that the field of biodiversity conservation has a lot to do with people and heterogeneity is critical.

What does a conservationist look like? According to the Bureau of Labor Statistics in 2013, 90.5% of environmental scientists were white (The Atlantic, 2013). Women still lag far behind men in total outdoor and wildlife industry employment (Camber Outdoors, 2017; Manfredo et al., 2018). But these facts do not tell the full story of Gen X, millennials, and Gen Z folks who consider themselves conservationists.

As a young generation of conservationists, we do not always reflect the traditional mold of career "-ists" before us: mammalogists, ornithologists, entomologists, ichthyologists. Standing on the shoulders of past ecologists and environmentalists, we have internalized 20th century lessons about the effects of fire suppression, pollution, and overharvesting. We have heard the phrase "novel challenges, novel solutions" for years now and we accepted the need to reframe traditional biomes to include anthropogenic effects earlier in our education. My generation is not made up of only Leopold-esque outdoors folk interested in game management. In graduate school, I witnessed the demand for more diversity and relevance—among faculty, students, and projects—in land-grant agricultural institutions. Many of us did not explicitly want to be trained as deer biologists, but neither did we only want to work with endangered species. We were encouraged to break the habit of introducing ourselves by study taxa and instead lead by conservation issue.

I cannot speak for all my peers, but I see young conservationists as having diverse values and unique motivations. I like working in cause-oriented teams. I believe in community service because I have seen it enhance people's sense of place, belonging, and agency, and seen those be strategically leveraged for conservation (Simon and Wang, 2002). I think a person's connection to the land, something hard to quantify but deeply ingrained, is a key to conservation (Allen et al., 2018). Understanding local contexts is critical to conservation success, even at the level of a family farm. Cruising around properties, hearing landowner's wildlife anecdotes and histories of familial land ownership is my idea of a well-spent field day. I do not think these interpersonal aspects make me less scientific. I also do not think I am alone in wanting to practice conservation in a way that embraces the potential of human contributions rather than disparaging them (e.g., contrast Terborgh's *Requiem for Nature*). As Wendell Berry says, conservationists should care about less glamorous environmental sectors like agriculture because "conservationists eat." Our common denominators are our human experiences which, because they shape our values (Chan et al., 2016), factor highly into the practice of conservation.

Many of us look to the future of conservation and heed the call to work "where humans live." We study marginal habitat, looking for opportunities for urban conservation, education, and outreach. Rather than scoffing at the statistical limitations of citizen science data, we recognize the potential it has for increasing awareness in otherwise isolated populations. We recognize the value of economic arguments to conservation messaging, but we are willing to take a step beyond payment for ecosystem services. We have been taught to be in a more nuanced zone, beyond such instrumental and intrinsic value approaches, and are ready to shift conversations and policy toward relational values (Chan et al., 2016). I have seen many friends engage older folks in conversation

on social media platforms to change their opinions on climate science because they feel it is worth the energy. These efforts require that we recognize how others form values and make decisions differently from us.

As with any problem-solving profession, conservation requires many skills and approaches, which requires many types of people. Conservationists work in academia, NGOs, or state and federal agencies with environmental science, sustainability, biology, ecology, wildlife, or natural resource degrees. But conservationists are also educators, engaging with young school groups about macroinvertebrates in neighborhood streams. They work in courts and statehouses, as environmental attorneys and non-scientist advocates. They are the volunteers who spend weekends improving trails and leading river cleanups. Conservationists are the coders and mathematicians who spend their days on the computer, developing Python scripts in ArcGIS for complex regional habitat analysis. They may not lay hands or eyes on the species or ecosystems they are studying, but they contribute no less than the field technician. Conservationists are the backyard naturalists and birders making notes about unusual patterns in phenology and migration. They are the young couples starting small-footprint but high-intensity farms to promote local agriculture and land sparing. Sometimes, conservationists have to practice in their free time and not as a primary profession. Sadly, this is becoming even more common as graduates struggle to get paid work and break into professional workplaces (Mongabay, 2017). While certainly not always the case in our polarized political climate, young people tend to be accepting of each other's differences (Black, 2010) and I trust we will continue to make space in our field for those with something to offer, even if they do not fit traditional molds.

Throughout various wildlife research projects, I have persistently asked "what else." What else can conservation work entail? I think a conservationist can come from many different places, but we are headed together into the same, though unknown, future. Welcoming a diversity of backgrounds and experiences can only lend us more collective insight, as we tackle more challenges in more places.

Turning Toward Others: Local, Bottom-Up Conservation Efforts

When I think of our conservation challenges for the future, I am not worried about our ability to do good science. We are building bodies of knowledge and advancing our understanding of ecological processes and systems in novel conditions. To me, a looming challenge is effectively practicing conservation. I think we need to focus on our communication—translating our messages and engaging with the right audiences in the right way. This may include some or all of the following:

- improving the public's trust in science,
- communicating well not just with each other but with the public and with policy makers,
- identifying and reaching all stakeholders involved,
- being receptive to new ways of doing things,
- utilizing unconventional but powerful platforms like social media to spread information (infographics, sound bites),
- and doing work that is interdisciplinary.

These all involve interactions with other people and reaching people that are different from us.

I have some ideas about how we might effectively engage others in tackling conservation issues, borne out of work I did at the Southern Appalachian Highlands Conservancy, a regional land trust where I served as an AmeriCorps member. The idea of service was not something advocated for by my academic advisors, but I was drawn to it—affecting change by empowering young leaders in target communities. Environmental conservation is a focus area of The Corporation for National & Community Service's AmeriCorps, although it is not as visible as public school programming or community revitalization (Simon and Wang, 2002). I decided this program would be a humbling way to pass time between college and graduate school and might help me process what I could contribute to conservation. I looked forward to getting out of the theory books and "getting things done" with non-academic folks working in land protection and stewardship. I am not surprised now to learn that AmeriCorps participants show marked changes in values as a result of their service experiences (Simon and Wang, 2002), but I did not expect then for mine to fundamentally change my mindset of conservation.

The service was rewarding and enriching. It taught me more about what various careers in conservation looked like than anything I had been exposed to in school. I learned about non-profit management, the dynamic nature of collaboration with state and federal agencies, and environmental issues specific to a place. I peeked into the legal side of land protection. Above all else, I learned about improving lands for the public good (whether publicly owned or not) and promoting responsible land stewardship. And on a personal level, I was encouraged and impressed by my passionate peers—fellow future conservationists—who lived and breathed their values.

One thing I did repeatedly in my AmeriCorps service was plan, lead, and execute volunteer workdays to improve trails, clean up trash, and control invasive species. These exhausting but exhilarating days came to represent something larger to me: the power and potential of bottom-up conservation.

Leading a good volunteer workday is a parable for practicing conservation. You have to identify your needs and the context, prepare for the work, gather your resources, recruit people, anticipate their needs to keep them happy, and reevaluate the problem at the end of your workday to see if you're going to need to plan another.

The issues behind these workdays involved multiple stakeholders, often with different values and objectives. Take the example of a trail workday on a conservancy-owned tract of land. This particular property was adjacent to National Forest Service land and was

an unintentional gateway for recreationalists. There is an impetus to apply best management practices on such properties, to be a good neighbor and example to others. The land trust would rather protect the water quality of trout streams at all costs by reducing erosion and limiting all impactful recreational activities upstream. But the land trust is subject to board members and the public, so it also experiences some pressure to keep their protected land open for public enjoyment. Also involved in the scenario is the local community—folks who are going to walk, bike, or 4-wheel across the property regardless of signs posted and who may not be aware of how their tread damages the land. Finally, there are the federal and state partners who lent support to the land protection in the first place—USFS and NC Wildlife Commission folks who have a vested interest in collective natural resources. Thus, we had to minimize threats to water quality while maximizing stakeholder satisfaction, and we had to hold a workday to redirect problematic spur trails and improve the grade and sustainability of the main trails.

A number of lessons I learned from coordinating these events can be applied to the future of conservation:

- (1) *Always begin with identifying the problem.* The problem was loose sediment from the unofficial trails washing into high quality trout streams. In conservation science, we have to start with knowledge: making observations, documenting and monitoring, and doing basic science.
- (2) *Plan and prepare.* The observations and knowledge from step 1 help you make a good plan for applying resources toward a particular problem.
- (3) *Have the right tools, or you can't get the work done.* Resources need to be in place before you start. It goes without saying that we need to match conservation problems with the appropriate resources (and this often also means securing sufficient funding). But beyond that, I think the right tools we can have as conservationists in the next generation are communication and critical thinking, on top of a solid foundation of scientific training. In fact, non-disciplinary skills like written/oral communication, leadership, and interpersonal training are desired by employers in multiple sectors (Blickley et al., 2013). Although not all that is required, this broader training will allow us to address varied problems.
- (4) *Success involves people.* None of the planning and preparation mattered unless we had people show up. The jobs were simply too big for the staff alone. Conservation issues have to be made relatable (why should a hiker care about erosion?) and actions/solutions have to be accessible (if you come help us improve a trail, you'll be helping protect water quality). When they arrived, you had to keep them there despite hard, unglamorous work. It was easier when doing a project with visible progress, like pulling invasive plants, but otherwise you needed to get them to learn or experience something new to make the day worthwhile.

Achieving this commitment often takes offering some sort of incentive. This is not unusual for conservation, especially in the private arena; it is a practical approach undertaken by many groups. USDA-NRCS cost-share programs offer assistance for producers to do best management practices that promote soil, water, or wildlife habitat health which may otherwise be prohibitively expensive for them. Land protection is a much easier sell when there are tax incentives, so conservation easement landowners experience an immediate payoff for waiving development rights on their land. Also, the USFWS has several agreements to make it easier on private landowners where threatened and endangered species are concerned. Our volunteers would be given the best experience possible while still getting important work done. Volunteers would be invited to use the trail they helped improve, and I would follow up with them later on with long-term results of their labor.

At the end of these days, people were dripping with sweat and dirt, aching for showers and running toilets. But they would feel they had done something tangible for the issue at hand. That lasting awareness is essential to getting more people committed and making messages stick.

- (5) *The final lesson about workdays was that there were always results I had not anticipated.* These volunteers had totally different backgrounds and day jobs, and sometimes ideologies, but they were unified by a shared love of the region we were working in, or a common value of community service. Sometimes we learn the most when we think we have complete control but we allow ourselves to be surprised by something we could not have predicted.

I believe the work of connecting people to land will be a successful conservation strategy because it transcends other boundaries and constructs. One can hold a land ethic and have various sociopolitical or economic leanings. Owning—or simply enjoying—unique spaces creates solid personal connections which endure because they involve so many senses. For example, hikers completing a trail earn a sense of ownership, hunters and farmers become keen and intuitive naturalists, volunteers invest a piece of themselves in service, and kids treat woods as their own personal playgrounds. Values derived from experiences are powerful (Chan et al., 2016). These authors explain that relational values contribute an important piece to the case for environmental protection—beyond simply intrinsic (for nature's sake) or instrumental (for human's sake) arguments. Such a framework considers the influence of cultural and individual identity, social responsibility and stewardship principles, and additional moral virtues in people's decision-making. Importantly, values are formed because of relationships, experiences, and connections to people and places. I think this is how conservation scales up and effects change: by involving people, keeping them coming back, and counting on them to spread awareness one step further. It is certainly how a group of about 30 AmeriCorps members increases education and awareness about conservation issues in Western North Carolina every year. It is how we could build better trails, establish new wildlife and pollinator habitat, clean up rivers and banks, and make space for native species. And if it takes a volunteer heart, then we ought to be cultivating that more in our peers and children.

Conclusion

Conservation is a broad and complex field that is more about people than I ever thought. It does not happen successfully in a vacuum and it requires innovation, partnership, and communication. We need to recognize that all of us have a worldview shaped by our experiences and we can probably come up with the best ideas if we acknowledge that wealth of diversity. We should listen humbly and be open to being transformed based on conversations with others. And, unfortunately, we cannot do that if we are all just wild girls living in the woods.
